INDEX TO VOLUME CXLIV.

Abbott, E. G. Oblique subtrochanteric osteotomy for the lengthening of the femur and correction of the deformity of flexion resulting from hip-joint disease, 351.
Abbott, S. W. Recent progress in public hygiene, 311, 332, 353.
Abdomen. Contusion of the abdomen, no external wound, rupture of the descending colon, fecal abscess, drainage, suture of ruptured gut, recovery, Scudder, C. L., 377; contusions of the abdomen, Scudder, C. L., 415; catharsis in abdominal surgery, Crandon, L. R. G., 639.
Abel, J. J. Further observations on epinephrin, 116.
Abscess. The treatment of psoas abscess by incision, Lovett, R. W., 463.
Academy of Medicine. Channing, W., 125.
Adams, Z. B. The differential diagnosis of intestinal obstruction, 12.
Adirondack Cottage Sanitarium, 538.
Advertisements. Disgraceful and annoying medical advertisements in current magazines and newspapers, Totten-McMaster-G., 569.
Allen, G. W. Treatment of chronic gonorrhea, 134.
"American Medicine." A new medical journal, 362.
Anatomy. The study of anatomy, 290.
Anesthesia. My failures and successes with spinal anesthesia, Marx, S., 17; remarks upon spinal cocainization suggested by cases seen at Tuffier's clinic in Paris, August, 1900, 37; the report of the anesthetics committee of the British Medical Association, 298; remarks on anesthesia—general, local and spinal, Richardson, M. H., 391, 407.
Antitoxin. The use of antitoxin, 341.
Appendicitis. Typhoid fever vs. appendicitis, Richardson, M. H., 26; is appendicitis increasing, 26?; inherited predisposition to appendicitis, DeWitt, W. H., 627; a case of measles complicated by appendicitis, Williams, H., 642.
Appetites and passions, 124.
Arm. Backward dislocation of the ulna, fracture of the external condyle of the humerus, fracture of the radius and ulna near the wrist joint, Beach, H. H. A., 206.
Army. The army bill and the medical department, 52; medical generals, 173; information for candidates seeking employment in the army, 244; meat ration in the tropics, Egan, F. R., 276; American soldiers in the tropics, Seaman, L. L., 598.
Arnold, H. D. The condition of the myocardium as affecting cardiac murmurs, 324, 335.
Arsenic in food and drink, 313.
Asthma. Emerson, F. P., 520.
Athletics. A study of the food consumed and digested by four members of the Harvard University boat crew in June, 1900, Atwater, W. O., and Benedict, F. G., 601; athletic training, 654.
Atwater, W. O., and Benedict, F. G. A study of the food consumed and digested by four members of the Harvard University boat crew in June, 1900, 601, 629.
Back Bay water park and the health of Boston, 386.
Bacteriology. A series of cases illustrative of the clinical importance of bacteriological examinations, Fitz, R. H., 207; the interpretation of bacteriological findings in diphtheria diagnosis, Hill, H. W., 226.
Bailey, P. Spinal accessory paralysis, 212; the nervous system in diabetes, 382.
Balch, F. G. Treatment of acute gonorrhea, 130.
Barker, Novy and Flexner. Study of bubonic plague based upon the outbreak in San Francisco, 564.
Barnes, H. J. The Charles River basin, 460.
Bartley, E. E. Hyperglycosuria and diabetes mellitus in relation to life insurance, 383.
Beach, H. H. A. Operation for the removal of a foreign body impacted in the esophagus for more than two weeks, 206; backward dislocation of the ulna, fracture of the external condyle of the humerus, fracture of the radius and ulna near the wrist joint, 206; retention of urine from obstruction by the third lobe of the prostate gland, 207.
Beck, C. The treatment of puerperal fever, 188.
Bell, R. Experience in search of a cure for asthma in the far Southwest, with observations of the comparative value of different sections in respiratory diseases, 395.
Bellevue Hospital. Report on conditions at Bellevue Hospital, New York, 172.
Beyer, H. G. Experiment and experience with the rifle, 1.
Bibliography. Abrams, A., diseases of the heart, 594; Anders, J. W., a textbook of practical medicine, 167; Ayers, E. A., physical diagnosis in obstetrics, a guide in antepartum, partum and postpartum examination for the use of physicians and undergraduates, 456; Beck, C., fractures, 320; Bennett, W. H., the present position of the treatment of simple fracture of the limbs, 119, on the use of massage and early passive movements in recent fractures and other common surgical injuries, and the treatment of internal derangements of the knee joint, 120; Bichat, X., anatomie générale appliquée à la physiologie et à la médecine, 593; Black, J. J., forty years in the medical profession, 359; Borden, W. C., the use of the Röntgen ray by the medical department of the U. S. Army in the war with Spain (1898), 167; Bryce, R., and Sherrington, C. S., the Thompson Yates laboratories report, 95; Brubaker, a compend of human physiology, 595; Bruce, J. M., Bruce's principles of treatment, 239; Buck, A. H., a reference handbook of the medical sciences, 358; Carpenter, G., the syphilis of children in everyday practice, 266; Carter, A. B., the prevention and cure of obesity, 144; Caton, R., the prevention of valvular disease of the heart, 144; Chapin, C. V., municipal sanitation in the United States, 620; Chapman, C. W., heart disease in childhood and youth, 19; Cheyne, W. W., and Burghard, F. F., a manual of surgical treatment, 94; Crile, G. W., experimental research into the surgery of the respiratory system, 143; Culbreth, a manual of materia medica and pharmacology, 594; Cutter, T. S., cancer of the uterus, 191; Curtis, H. J., the essentials of practical bacteriology, 360; Cushing, A. R., a textbook of pharmacology and therapeutics, or the action of drugs in health and disease, 167; Da Costa, J. C., modern surgery, general and operative, 21; Davis, E. P., obstetric and gynecologic nursing, 359; De Keersmaecker, J., and Verhoogen, J., chronic urethritis of gonococcic origin, 479; Dunglison, R., a dictionary of medical science, 506; Dwight, T., description of the human spines showing numerical variations in the Warren Museum of the Harvard Medical School, 142; Eccles, W. McA., hernia, 20; Eastes, W. L., the treatment of fractures, 71; Evans, D. J., Evans's obstetrics, 407; Golebiewski, E., atlas and epitome of diseases caused by accident, 93; Goodrich, W. F., the economic disposal of town refuse, 622; Goodsall, D. H., diseases of the anus and rectum, 408; Gould, G. M., suggestions to medical writers, 93; Greene, C. L., the medical examination for life insurance and its associated clinical methods, 191; Haig, A., uric acid as a factor in the causation of disease, 95; Hare, H. A., a textbook of practical therapeutics, 95; Harrington, C., a manual of practical hygiene for students, physicians and medical officers, 456; Harvard College: annual report, 1899-1900, 144; Hine, T. W., practical guide to the public health acts, 288; Hopkins, W. B., a clinical treatise on fractures, 93; Hunter, W., on sepsis as a cause of septic gastritis, "toxic neuritis" and other septic conditions, 408; Hutchinson, W., studies in human and comparative pathology, 456; international catalogue of scientific literature, 283; Jackson, E., a manual of diagnosis and treatment of diseases of the eye, 20; Joseph, M., and Loewenbach, G., dermatobiological technique, 46; Keetley, C. B., orthopedic surgery, 167; Kelynack, T. M., and Kirkby, W., arsenical poisoning in beer drinkers, 313; Kirkes' physiology, 27; Knopf, S. A., tuberculosis as a disease of the masses and how to combat it, 478; Krafft-Ebing, R. von, psycopathia sexualis with special reference to antipathic sexual instinct, 190; Kyle, D. B., a textbook of diseases of the nose and throat, 384; Manson, P., tropical diseases, 144; Mayo, T. J., consumption, pneumonia and their allies, 594; McBride, P., diseases of the throat, nose and ears, 21; Morrell, S. H., rudiments of modern medical electricity, 191; Morris, M., ringworm in the light of modern research, 72; Munson, E. L., the theory and practice of military hygiene, 623; Musser, J. H., Musser's diagnosis, 150; Mynter, H., appendicitis and its surgical treatment, 94; Packard, F. R., the history of medicine in the United States, 480; Parkes, L., and Kenwood, H., hygiene and public health, 621; Payne, J. F., Thomas Sydenham, 593; Peiper, E., insect larvæ as occasional parasites in man, 46; Porter, W. T., an introduction to physiology, 287; Powell, W. M., Saunders' question compends, 621; Pryor, W. R., the treatment of pelvic inflammation through the vagina, 240; Pyle, W. L., a manual of personal hygiene, 190; Roberts, J. B., a manual of modern surgery, 19; the surgical treatment of congenital and pathological disfigurements of the face, 95; Robson, A. W. M., diseases of the gall bladder and bile ducts, including gall stones, 94; a guide to the instruments and appliances required in various operations, 95; Roger, G. H., introduction to the study of medicine, 191; Schamberg, J. F., a compend of diseases of the skin, 72; Sehn, N., medico-surgical aspect of the Spanish-American war, 456; Seitz, C., Kurzgefasstes Lehrbuch der kinderheilkunde für Aerzte und Studirende, 72; Senn, N., the pathology and surgical treatment of tumors, 94; Snell, S., on the prevention of eye accidents occurring in trade, 47; Solis-Cohen, S., and Eshner, A. A., Saunders' question compends, No. 17, 167; Stimson, L. A., a practical treatise on fractures and dislocations, 72; a manual of operative surgery, 73; Stöhr, P., textbook of histology, including microscopic technique, 166; Stoney, E. M. A., bacteriology and surgical technique for nurses, 20; Sturgis, F. R., the students' manual of venereal diseases, 384; sexual debility in man, 505; Swanzy, H. R., a handbook of the diseases of the eye and their treatment, 21; Taylor, J. M., and Wells, W. H., manual of the diseases of children, 359; Thomas, J. B., Jr., a book of detachable diet lists for various diseases, 46; Thoring-

ton, J., refraction and how to refract, 46; Thornton, E. Quin, the medical news pocket formulary, 654; Thorpe, E. J. E., speech hesitation, 95; Tirard, N., Tirard's medical treatment, 143; Treves, F., the tale of a field hospital, 191; Tyson, J., the practice of medicine, 19; Walsham, W. J., surgery, its theory and practice, 73; Warren, J. C., and Gould, A. P., the international handbook of surgery, 47; Wilbur, C. L., the thirty-second annual report of the Secretary of State on the registration of births, deaths, marriages and divorces in Michigan for the year 1898, 93; Williams, D., medical diseases of infancy and childhood, 45; Winters, J. E., the feeding of infants, 594; Wood, H. C., therapeutics, its principles and practice, 95.

Billings, F. Report on the progress of cases of pernicious anemia presented to the association in 1900, and report of a case of pernicious anemia with diffuse spinal cord lesions with post-mortem findings, 562.

Billings, J. S. Remarks at the dedication of the new building of the Boston Medical Library, 61.

Biography. Baker, R. C., 438; Barclay, P. M., 198; Bixby, G. H., 245; Bond, F., 198; Booth, A. R., 54; Bradley, E., 294; Brockway, F. J., 438; Brown, U. H., 28; Burge, J. H. H., 342; Busey, S. C., 197; Carradine, J. S., 438; Cogswell, G., 414; Comfort, J. E., 570; DaCosta, J. M., 169; Deyo, A., 462; Dorr, S. G., 462; Draper, W. H., 436; Dunglison, R. J., 269; Dresser, A. J., 658; Feeney, J. L., 570; Ferris, I. W., 28; Fodor, J., 508; Franklin, B., 198; Greenleaf, R. W., 438, 459; Giddings, T., 246; Gregg, S. C., 150; Hamilton, E. E., 126; Hayes, J., 512; Hayward, G., 342; Herrick, H. J., 126; Hill, H. C., 174; Hodgman, A., 246; Hyde, S. T., 222; Inglis, R., 438; Jacob, A. H., 173; Jewett, H. O., 150; Lazear, J. W., 596; Lee, L. J. W., 78; Levison, H. A., 318; Linsley, J. H., 219; Lyon, S. K., 462; Manassein, Professor, 315; Marston, D. W., 628; McDonough, L. J., 438; Mergler, M. J., 537; Miller, T. De C., 150; Montford, R. V. K., 54; O'Callaghan, T. A., 540; Ollier, L., 269, 569; Osborne, G. S., 540, 568; Palmer, H. O., 540; Parkhill, M. H., 342; Potter, H. B., 222; Rice, C., 511; Riley, T., 246; Rosse, I. C., 486; Sargent, J., 318; Shurtleff, A., 126; Smith, E. A., 28; Sprague, S. B., 600; Stevens, C. W., 126; Stronach, J. W., 126; Sumner, A. M., 540, 568; Tarbell, G. G., 28, 52; Thayer, F. L., 246, 269; Warren, E. L., 540; Weingee, C., 540; Wells, J. A., 540; Wheeler, T. B., 78; Whitbeck, H. D., 540; Worcester, W. L., 627; Wren, G. W. C., 318; Youmans, W. J., 390.

Blake, J. B. Gonorrheal prostatis, 137; sarcoma of the humerus and scapula, 645.

Blake, J. G. Registration of midwives, 91.

Blodgett, A. N. Formaldehyde gas in diphtheria, 412.

Blood. Study of granular degeneration of the red blood corpuscles, Stengel, A., White, C. Y., and Pepper, W., 563; the effect on the blood of ether as an anesthetic, DaCosta, J. C., and Kalteyer, J. L., 580; examination of the blood in relation to surgery of scientific value, but too often of no practical value, and may misguide the surgeon, 591.

Body. The right to will one's body for scientific investigation, 317.

Boland, E. S. The woollen yarn truss in infantile inguinal hernia, 152, 169; remarks at meeting of the Suffolk District Medical Society, 433.

Boldt, H. J. Specimen of tubal pregnancy, 213; the definition of septicemia and pyemia; the indication for vaginal hysterectomy and for abdominal section and drainage in puerperal fever, 214.

Bone. Osteitis deformans, Packard, F. A., and Steele, J. D., 587; the spinal form of arthritis deformans, Osler, W., 588.

Boston. Boston's ice, 537; a menace to Boston's water supply, 565.

Bowen, J. T. Report on dermatology, 186, 209.

Bradford, E. H., and Cotton, F. J. Progress in orthopedic surgery, 108, 141, 158.

Brandy. What is brandy? 172.

Bread. Good bread and sanitary bakeries, 217.

Brookline, Report of Brookline, Mass., board of health, 361.

Brothers, A. Malignant chorion epithelioma, or so-called deciduoma malignum, 16.

Brown, F. T. The diagnosis and surgical treatment of renal tuberculosis, 513, 527.

Brush and Fayerweather. Observations on the blood pressure during the period of normal sleep, 91.

Bryant, J. D. The influence of mental depression on the development of malignant disease, 589.

Bubonic Plague. Curry, J. J., 277.

Bullard, W. N., and Townsend, C. W. Convulsions in children, 233, 239.

Burrage, W. L. Gonorrhea in women, 132.

Burrell, H. L., Lovett, R. W., and Goldthwait, J. E. Report of cases from the second surgical service of the Children's Hospital, 329.

Burrell, H. L., and Cushing, H. W. Report on progress of surgery, 429, 451, 476, 495.

Cabot, A. T. A case of accidental inoculation of cancer in a fresh wound, 471; photograph of an artificial anus following a Krasko's operation for cancer of the rectum, 474; idiopathic abscess of the kidney, 554; some forms of intestinal obstructions due to adhesions, 625, 646.

Call, E. A. A case of Cæsarean section in a face presentation, complicated by uterine fibroid, 427, 431.

Cancer. A case of accidental inoculation of cancer in a fresh wound, Cabot, A. T., 471; another alleged cause of cancer, 480; notes on the treatment of some forms of cancer by the x-rays, Williams, F. H., 587; some phases of the cancer question, Park, R., 588; brief consideration of the cases of cancer of the breast treated at the Johns Hopkins Hospital since 1889, Halstead, W. S., 589; late results in inoperable sarcoma treated with the mixed toxins, Coley, W. B., 589; the influence of mental depression on the development of malignant disease, Bryant, J. D., 589; some statistics of cancer, 595.

Cary, C. A case of pneumonia complicated by pseudo-membranous exudate on the mucous membranes of the mouth, tongue, pharynx, nares, conjunctivæ, glans penis, anus, etc., caused by diplococcus pneumoniæ, 562.

Celli, A. Malaria in relation to engineering and agriculture, 364.

Census. A census of tuberculosis, 655.

Century. MDCCC-MCM, 22.

Cæsarean Section. A case of Cæsarean section for complete placenta previa, Hare, C. H., 151, 160; a case of Cæsarean section, Keenan, H. J., 255; a case of Cæsarean section in a face presentation, complicated by uterine fibroid, Call, E. S., 427, 431.

Chadwick, J. R. Address at the dedication of the new building of the Boston Medical Library, 56.

Channing, W. An academy of medicine, 125.

Chapin, H. D. A simple and accurate method of substitute infant feeding, 166; diabetes in children, 382.

Charles River Basin. Barnes, H. J., 460.

Charities. Report of joint committee of State Charities Aid Association, 436.

Charity. The blessings of charity, 568.

Cheever, D. W. Address at the dedication of the new building of the Boston Medical Library, 56.

Children. The purulent rhinitis of children as a source of infection in cervical adenitis, Cobb, C. M., 38; report on the diseases of children, Rotch, T. M., 66; a simple and accurate method of substitute infant feeding, Chapin, H. D., 166; convulsions in children, Bullard, W. N., and Townsend, C. W. 233, 239; whey cream modifications in infant feeding, White, F. W., and Ladd, M., 257; report of cases from the second surgical service of the Children's Hospital, Burrell, H. L., Lovett, R. W., and Goldthwait, J. E., 329; pathology of the newborn as illustrated in the practice of the writer, Taylor, F. W., 347, 357; diabetes mellitus in children, Chapin, H. D., 382; infantile scorbutus, Morse, J. L., 465; shall it be sunlight or sleep for children; which is the more effective agent for general health, 485.

Christian Science. A so-called victory for Christian Science, 362.

Chute, A. L., and O'Neil, R. F. Some observations on chronic seminal vesiculitis, 577.

Circulatory System. The suprarenal capsule in organic heart disease, Floersheim, S., 77; observations on the blood pressure during the period of normal sleep, Brush and Fayerweather, 91; some new observations on blood plates and leucocytes, Kemp, G. T., and Calhoun, H., 92; the treatment of the later phases of heart diseases, Heffron, J. L., 103; fatty degeneration of the heart, Satterthwait, T. E., 105; rupture of the right iliac artery, Shattuck, F. C., 183; pleuropericardial and diaphragmatic adhesions, Goodwillie, D. H., 188; recent progress in thoracic diseases, Sears, G., and Bartol, J. W., 236, 256; diseases of the myocardium, Jackson, H., 319, 335; the condition of the myocardium as affecting cardiac murmurs, Arnold, H. D., 324, 335; an undescribed cardiac sound, Hare, H. A., 534; frequency and the diagnosis of the Flint murmur in aortic insufficiency, Thayer, W. S., 534; the causes and clinical features of cardiac hypertrophy, Stengel, A., 535; study of granular degeneration of the red blood corpuscles, Stengel, A., White, C. Y., and Pepper, W., 563; a case of marked cyanosis, difficult to explain, McKeen, S. F., 610; the treatment of the arteriovenous aneurisms of the subclavic vessels, Matas, R., 616; phlebitis following abdominal operations, Vanderveer, A., 617.

Clark, G. P. Rheocord, 92.

Clark, J. P. Case operated on for exaggerated Roman nose, 493.

Cleghorn, A. Kirkes' handbook of physiology, 125.

Cobb, C. M. The purulent rhinitis of children as a source of infection in cervical adenitis, 38.

Cobb, F. C. Peritonsillar abscess, 106, 112.

Cocoanut. Changes in the composition of the cocoanut during germination, Kirkwood, J. E., and Gies, W. J., 119.

Codman, E. A. No practical danger from the x-ray, 197.

Coggeshall, F. A case of complete placenta previa, 157, 160.

Coley, W. B. Late results in inoperable sarcoma treated with the mixed toxins, 589.

Collins, C. L. A brief summary of nine cases of lobar pneumonia treated by ice pack, 309.

Conn, G. F. John W. Pray prize—a correction, 657.

Coolidge, A. Jr. Progress in laryngology, 87.

Correction. John W. Pray prize—a correction, Conn, G. P., 657.

Cragin, E. B. Full-term ectopic gestation, 15.

Crandon, L. R. G. Catharsis in abdominal surgery, 639.

Crook, J. K. Recent progress in the treatment of acute lobar pneumonia, 164.

Culls, H. M. Upon what sort of information shall a medical examiner hold a view, 373.

Cumston, C. G. Intestinal anastomosis, 251.

Curry, J. J. A description of the work of the army pathological laboratories, and general remarks on the investigation of the diseases of the Philippines, 175; dysenteric diseases of the Philippine Islands, with special reference to the ameba coli as a causative agent in tropical dysentery, 177; bubonic plague, 277; the fevers of the Philippines, 446.

Cutaneous System. Cases of xeroderma pigmentosum, White, J. C., 473; case of elephantiasis, Vickery, H. F., 474; what is rodent ulcer, Fordyce, J. A., 164; report on dermatology, Bowen, J. T., 186, 209; a further report on the treatment of epidermoid cancer, Williams, F. H., 329; cutaneous complications in diabetes mellitus, Sherwell, S., 382; a case of ichthyosis in a boy four years old, White, J. C., 472; dermatitis produced by a caterpillar, White, J. C., 599.

Cutler, E. G. A short abstract of the early history of medicine in Massachusetts to the year 1800, 79.

DaCosta, J. C., and Kalteyer, J. L. The effect on the blood of ether as an anesthetic, 580.

Dana, C. L. Progressive lingual hemiatrophy, 213.

Darling, E. A. The effects of training, 556.

Davis, N. S., Jr. Internal medicine in the nineteenth century, 571.

Deaths in Boston for the years 1899 and 1900, 293.

Derby, H. The use and abuse of spectacles, 199.

Dewis, J. W. Placenta previa centralis, report of a case, 157, 161.

DeWitt, W. H. Inherited predisposition to appendicitis, 627.

Diabetes. Discussion, diabetes mellitus: diagnosis and prognosis, Stark, H. S., 380; etiology and pathogenesis, Stern, H., 381; diabetes in children, Chapin, H. D., 382; the nervous system in

diabetes, Bailey, P., 382 ; cutaneous complications, Sherwell, S., 382 ; ocular manifestations, Hepburn, N. J., 382 ; treatment, Mayer, A., 383 ; glycosuria and diabetes mellitus in relation to life insurance, Hartley, F. H., 383; the auto-intoxication of diabetes and its relation to prognosis, Herter, C. A., 563; metabolism in diabetic coma, with special reference to acid intoxication, Joslin, E. P., 564.

Digestive System. The differential diagnosis of intestinal obstructions, Adams, Z. B., 12 ; typhoid fever *vs.* appendicitis, Richardson, M. H., 26 ; on the movements of the esophagus and the cardia and on some of the complexities of the centre of deglutition, Meltzer, S. J., 91 ; a hair cast of a living human stomach, Jackson, N., 92 ; a case of idiopathic dilatation of the colon, Richardson, M. H., 155 ; a hair cast of the stomach, its successful removal by laparotomy, Jackson, N., 189 ; operation for the removal of a foreign body impacted in the esophagus for more than two weeks, Beach, H. H. A., 206 ; clinical notes and comments : cancer of the extremity of the common bile duct, Edes, R. T., 223 ; intestinal anastomosis, Cumston, C. G., 254 ; a case of retroperitoneal lymphangiosarcoma, operation, recovery, no recurrence after two years, Lund, T. B., 279 ; photograph of an artificial anus following a Kraske's operation for cancer of the rectum, Cabot, A. T., 474; the surgical treatment of gastric ulcer, with report of cases, Lund, F. B., 548, 559; cyst of the omentum, Jacobi, A., 561; septic infection through the stomach and duodenum, James, W. B., 586; pancreatitis with especial reference to chronic pancreatitis, Robson, A. W. M., 591; the surgical treatment of chronic ulcer of the stomach and duodenum, W. M., 615; an operation for the radical cure of umbilical hernia, Mayo, W. J., 618; prevention and cure of post-operative hernia, Moore, J. E., 618; inherited predisposition to appendicitis, DeWitt, W. H., 627.

Diphtheria. Disinfection within and without the body in diphtheria, Veeder, M. A., 153 ; the interpretation of bacteriological findings in diphtheria diagnosis, Hill, H. W., 226 ; formaldehyde gas in diphtheria, Blodgett, A. N., 412; diphtheria and boards of health, 566.

Disinfection within and without the body in diphtheria, Veeder, M. A., 153.

Doctor. A new kind of doctor, 97.

Draper, F. W. Remarks at the dedication of the new building of the Boston Medical Library, 58.

Dulles, C. W. Mumps in pneumonia, boroglyceride, 308.

Dunham, T. Iodophilia, 580.

Ear. Two cases of ligature of the internal jugular vein for infective thrombosis of the sigmoid sinus due to purulent otitis media ; one recovery and one death, Jack, F. L., 203; recent progress in otology, Hammond, P., 523.

Edes, R. T. Clinical notes and comments ; degenerative disease of the spinal cord associated with anemia, 10 ; clinical notes and comments ; cancer of the extremity of the common bile duct, 223.

Editorials. MDCCC-MCM, 22 ; underpaid physicians of public institutions, 22 ; ratio of physicians to the population, 47 ; physical culture, 48 ; the Boston Medical Library, 73 ; the responsibility of the doctor, 74 ; the thirty-first annual report of the State Board of Health of Massachusetts, 96 ; the registration of midwives, 97 ; a new kind of doctor, 97 ; report of the medical department in the Philippines, 120 ; mosquitoes and yellow fever, 122 ; the British congress on tuberculosis, 122 ; annual report of Harvard College, 144; gonorrhea from a medico-legal standpoint, 146 ; compulsory disinfection in typhoid fever, 168 ; a psychophysical laboratory in the Department of the Interior, Washington, 169 ; a proposed memorial to Dr. Da Costa, 169 ; some curiosities of legislative literature, 192 ; a school of tropical medicine in the Philippines, 194 ; the needs of a medical library, 216 ; good bread and sanitary bakeries, 217 ; a hospital for tuberculosis in Boston, 240 ; report of the New York tenement-house commission, 242 ; topography of the lateral ventricles 266 ; is appendicitis increasing, 267 ; the reports of the anesthetics committee of the British Medical Association, 288 ; the study of anatomy, 290 ; arsenic in food and drink, 313 ; associate membership in the Boston Medical Library, 315 ; the etiology of yellow fever, 337 ; the American Association of Pathologists and Bacteriologists, 339 ; plague in South Africa, 360 ; report of Brookline, Mass., Board of Health, 361 ; *American Medicine*, a new medical journal, 362 ; a so-called victory for Christian Science, 362 ; restrictive medical legislation, 385 ; the epidemic of typhoid fever at New Haven, Conn., 386 ; the proposed Back Bay water park and the health of Boston, 386 ; pathology of the Jewish race, 408 ; Instructive District Nursing Association, 409 ; hospitals in Japan, 433 ; two public documents, 434 ; defeat of the bill to regulate vivisection, 434 ; the preventive treatment of rabies, 457 ; the prevalence of smallpox, 457 ; another alleged cause of cancer, 480 ; a municipal hospital for pulmonary tuberculosis, 482 ; new light on the cause of pancreatitis, 506 ; a new medical laboratory for the University of Pennsylvania, 507 ; the illegal sale of narcotics, 508 ; some relations of medicine and surgery, 535; hospital corps graduation at Manila, 536; Boston's ice, 537; a menace to Boston's water supply, 565 ; a Rockefeller Institute for Medical Research, 565; diphtheria and boards of health, 566; some statistics of cancer, 595; one hundred and twentieth anniversary of Massachusetts Medical Society, 596; a proposed memorial to Jesse William Lazear, M.D., 596 ; a reorganization of the American Medical Association, 597 ; the Massachusetts Medical Society dinner, 622 ; physicians and the law, 623; meeting of the American Neurological Association, 624; athletic training, 654; a census of tuberculosis, 655.

Egan, P. R. Meat ration in the tropics, 276.

Electricity. Electric automobiles a source of electric light, Stedman, J. C., 101.

Elephantiasis. Case of elephantiasis, Vickery, H. F., 474.

Elliot, J. W. Case of stone in the ureter located by the x-ray, 475 ; prostatectomy by the combined method (Alexander), 475.

Emerson, F. P. A special form of phlegmon of the neck, 403; asthma, 520.

Ewing, J. A case of malarial nephritis, with massing of the parasites in the kidney, 586.

Experts. The opinion evidence of medical experts, McLaughlin, J. D., 367.

Eye. The radical treatment of lachrymal diseases, Lancaster, W. B., 34, 43 ; an operation for cataract, Parks, E. L., 37, 43 ; oculists and opticians, McKeon, J. E., 53 ; gonorrheal conjunctivitis, Williams, C. H., 139 ; esophoria or latent squint, Valk, F., 164 ; the use and abuse of spectacles, Derby, H., 199 ; destruction of left eye and frontal lobe of brain from a shotgun explosion, Swasey, E., 230; ocular manifestations in diabetes mellitus, Hepburn, N. J., 382 ; neuritis recurring after atrophy of both optic nerves in a case of brain tumor, Williams, E. R., 469.

Femur. Oblique subtrochanteric osteotomy for the lengthening of the femur and correction of the deformity of flexion resulting from hip joint disease, Abbott, E. G., 351.

Finger. Avulsion of the finger, with a case in which this accident occurred to an infant twenty months old, Monks, G. H., 201.

Fisher, E. D. Differential diagnosis in diseases of the spinal cord, 188.

Fitz, R. H. A series of cases illustrative of the clinical importance of bacteriological examinations, 207 ; idiopathic dilatation of the colon, chronic rheumatic arthritis, chronic mitral endocarditis, hemiplegia, embedded needle, 208 ; myxedema, 475.

Flexner. Study of bubonic plague, 585.

Floersheim, S. The suprarenal capsule in organic heart disease, 77.

Food. A simple and accurate method of substitute infant feeding, Chapin, H. D., 166 ; good bread and sanitary bakeries, 217 ; whey cream modifications in infant feeding, White, F. W., and Ladd, M., 237 ; meat ration in the tropics, Egan, P. R., 276 ; the dangers of boiled milk, 292 ; whey cream modifications in infant feeding, Miller, D. J. M., 340; a study of the food consumed and digested by four members of the Harvard University boat crew in training, 1900, Atwater, W. O., and Benedict, F. G., 601, 629.

Fordyce, J. A. What is rodent ulcer, 164.

Fractures. A new method of treating fractures, Hatch, L. F., 305.

Fried, G. A., and Gies, W. J. Does muscle contain mucin, 117.

Fuller, E. Results following the cure of chronic defects in the vesical function, 125.

Gage, H. Uterine fibroids, 179.

Gay, W. F. Echinococcus of the liver with perforation into the lungs and bronchi, 492.

Generals. Medical generals, 173.

Generative System. Large multilocular fibroma of the uterus, Janvrin, J. E., 16 ; cancer of the uterus, Janvrin, J. E., 16 ; a case of obliteration of the right ureter by a calcified fibroid ; removal of fibroid and implantation of the ureter into the bladder, recovery, Richardson, M. H., 83, 91 ; uterine fibroids, Gage, H., 178 ; specimen of large myomatous growth of the uterus, Janvrin, 213 ; some observations on chronic seminal vesiculitis, Chute, A. L., and O'Neil, R. F., 577 ; recent progress in gynecology, Lund, F. B., 583, 611 ; orchitis complicating typhoid fever, Kinnicutt, F. G., 587.

Gonorrhea. Gonorrheal infection, Tenney, B., 127 ; the bacteriological diagnosis of the gonococcus, Richardson, O., 129 ; treatment of acute gonorrhea, Balch, F. G., 131 ; gonorrhea in women, Burrage, W. L., 132 ; treatment of chronic gonorrhea, Allen, G. W., 134 ; the seminal vesicles in gonorrhea, Scudder, C. L., 136 ; gonorrheal prostatitis, Blake, J. B., 137 ; gonorrheal conjunctivitis, Williams, C. H., 139; when is a gonorrhea cured, Thorndike, P., 140 ; gonorrhea from a medico-legal standpoint, 146.

Goodale, J. L. Retropharyngeal abscess in the adult, 108, 112.

Goodwillie, D. H. Pleuropericardial and diaphragmatic adhesions, 188.

Gorgas, W. C. The sanitary condition of Havana, 411.

Gunshot Wound. Operation for gunshot wound, Porter, C. A., 208.

EXPERIMENT AND EXPERIENCE WITH THE RIFLE.[1]

BY HENRY G. BEYER, M.D., U. S. NAVY.

In these uncertain and turbulent times when the peace balance of foreign relations has reached so high a degree of sensitiveness as to be disturbed and upset by a breath; when war clouds start up most unexpectedly and from the most unlooked-for quarters of the globe, and chase each other in rapid succession, the study of military surgery claims a much larger share of the attention of the medical student than ever before. Within the last two years a very considerable amount of knowledge has been harvested on the field of battle, and presented to us in the shape of some of the most excellent monographs ever written on the subject. Every student of military surgery, taking his profession seriously, and, therefore, seeking every available opportunity to inform himself and keep abreast with the times, must feel a debt of gratitude for the very instructive reports that have come to him and the profession from Senn, Nancrede, La Garde, Borden, Sir William MacCormac, Treves, Dent, and many others.

There has, perhaps, never been a time in the whole history of field operations, when any one particular weapon has wielded so powerful an influence on both friend and foe, professional soldier as well as layman, and on the military medical man, as has the present infantry rifle. The influence of the practical work of this gun in the field upon both offensive and defensive operations, upon the disciplined courage of the soldiers, upon future drills and upon the handling of the wounded, both during and after the battle, has, perhaps, not yet been fully measured and realized. Enough, however, has already been done and accomplished to bring us to a full sense of realization of the great and overwhelming importance of the present infantry rifle.

When we consider that, at the battle of Colenso, in the Anglo-Boer War, 97.5% of all the wounds were due to rifle fire, and only 2.5% to shell fire, an intimate study and acquaintance of the work done by this phenomenal piece of machinery, on the part of the surgeon, ought to need no further argument. In order that the conclusions which have been reached and formulated shall prove enduring and useful in the future, it would seem both desirable as well as necessary for us to carefully weigh and measure the evidence that has so far accumulated on both the experimental and practical side of the question. Before going into the details of either side, let us once for all keep in mind the more general as well as significant fact, also the result of recent experience in the field, that the proportion of the killed to the wounded, a proportion of 1 : 4, remains nearly the same as in former wars, although the percentage number of recoveries from among the wounded has been largely increased under the new bullet. There seems to be, moreover, little doubt on the part of the most experienced military surgeons that, after all shall have been said and sifted with regard to the humane character of the new bullet, and after due and proper allowance shall have been made for the influence of antiseptic methods of surgery, the palm of humanity will be found to belong as much to Lister, the man who originated antisepsis in 1876, as to Reger, the man who introduced the steel-jacketed bullet in 1884. With regard to this point Dr. Borden says ("Gunshot Wounds"): "I venture to say that had modern methods of asepsis and antisepsis been in use during our Civil War, the results would have been so different from those actually obtained, that it would have been seen that it was the surgical method employed, and not the particular bullet, which most influenced the result . . . It was probing with dirty probes and unclean fingers, and unnecessary operative interference under septic conditions and septic dressings, that was responsible for unfavorable results and high mortality."

With these general facts in mind, let us first turn our attention to the side of the experimenter.

A close and careful study of that most excellent monograph by Kocher, "Zur Lehre von den Schusswunden," Cassel, 1895, cannot help but result in showing that almost every injury produced by the new bullet that has been described so far as having occurred in the field has its prototype among the experimental results recorded in that work and the rest will find a most satisfactory explanation. The conscientious, unbiased and discriminating student, looking for the grand principles underlying the production of gunshot wounds, and not for the minor and non-essential details that were merely deduced, will find himself richly rewarded by a perusal of this work.

Let us, therefore, spend a short time in turning our attention to the contents of this monograph and the splendid illustrations that accompany the same. From it we learn that Kocher has experimented annually for a period of nearly twenty years, and his chief merit consists in that he has furnished the best explanation of the nature and the manner of production of what is known as *explosive effect*. From my own limited experience with experimental injuries, I may be permitted to say right here that, when once the peculiar conditions under which this explosive effect is produced are thoroughly known and correctly appreciated by the student of military surgery, the whole subject of gunshot injuries and their production under the most varied conditions, on either the living or the dead, in the field or in the laboratory, becomes unexpectedly clear.

Explosive effect in general has been attributed by different observers to a variety of causes and conditions, namely: (1) To deformed and deforming bullets; (2) to indirect or ricochet shots; (3) to the rotation of bullets; (4) the melting of the lead of the bullet.

Kocher, while willingly admitting, and, thereby, basing himself on his own experiments, that any and all the above-named conditions may co-operate in its production, sees in none of them the principal and primary cause of the explosive effect, inasmuch as he has produced the effect by undeformed, non-rotating and non-melting bullets, providing he gave these bullets the required velocity. According to Kocher, moreover, explosive effect, whether occurring in dry substances or in organs saturated with water, is due to and may be explained by the operation of the same physical law.

As early as 1880, now twenty years ago, Kocher had demanded that it should be made a matter of international law and agreement to introduce metals in

[1] Read before the Boston Society for Medical Improvement, November 26, 1900.

the manufacture of projectiles that possessed a higher melting point, greater hardness and a smaller diameter than the ordinary leaden bullets used at that time. He had already, then, convinced himself by experiment and observation that every increase in the frontage or the cross area of the attacking surface of a projectile was followed by diminished penetration and an increased explosive effect. It made no difference whether this surface was peculiar to the size of an original bullet or whether it was secondarily produced by deformity of a smaller bullet, owing to greater velocity being given to it than it could bear without becoming deformed.

Kocher, therefore, demanded that every further increase in the velocity given to any bullet should at once be compensated for by giving it a correspondingly increased hardness, because that alone could prevent the conversion of a small calibre projectile into one of large calibre by deformity on impact.

It was upon principles such as these that the early experimenters worked and succeeded in counteracting and correcting the disadvantages to mankind growing out of the higher velocities given to bullets for merely technical reasons; and so successfully did they struggle and do their unselfish work that today, it may be said, it is chiefly owing to these humane efforts on the part of experimenters that explosive effects for the human body have been practically eliminated from every part of it, except the very hardest portions of bone and those organs that contain a large percentage amount of fluids in their composition. That this is true, recent experience in war has so fully demonstrated as to produce almost the impression of disappointment upon the surgeons, not acquainted with either the views or the results of experimenters. Whence, otherwise, the seeming embarrassment on the part of some surgeons with regard to the lodgment of bullets; for instance, that low velocity bullets, no matter what their calibre, must arrive at a point where they will no longer penetrate is in perfect accordance with and not "despite all theory and experiment" (Nancrede). If none of that "appalling destructiveness" attributed to the new projectile, which experiment, made on the dead body and on animals, appeared to forecast, was seen, it was simply a matter of range or the low velocities by which the particular injuries referred to were produced.

The question as to whether the interest of the individual has overridden that of the State, by the reduction of the calibre of the bullet, or whether it has not, does not so much interest the surgeon as it does the professional soldier; it is enough for us to bear in mind that it was one of the aims of experimenters to produce a bullet that should be less destructive on the human body than the old leaden bullet. That this has been actually accomplished, recent experience has confirmed.

In order to make accurate comparisons between the effects produced by bullets of different dimensions and compositions, at varying distances from the muzzle, it became very desirable, soon after systematic experiments were begun, to have the objects of experiment near enough for accurate aiming and still strike that object with a velocity which should exactly correspond to that which the bullet would develop at any desired distance from the muzzle. The curve which a bullet describes from the time it leaves the gun to the moment when it falls to the ground is known as its trajectory. A bullet develops its greatest velocity a few feet from the muzzle of the gun. From that moment it steadily decreases until the bullet strikes the ground. The velocities which bullets develop at different distances have been ascertained for most of them and are, therefore, known. (Tables A and B).

By reducing the amount of our ammunition we may give any bullet such a velocity close to the muzzle as will accurately correspond to that which a full ammunition bullet would develop at any desired distance from the muzzle. Heppner and Garfinkel were the first to make experiments with such charges of reduced ammunition and Kocher finds that the alleged differences in the injuries produced, as compared to those at real distances, are so slight and uncertain that they might easily be explained on other grounds.

Kocher's experiments are so numerous and cover such an immense ground in time, scope, skill and material; they were done under conditions so varied, that it would seem as if the field had been thoroughly and absolutely exhausted. The velocities with which he experimented varied from 25 m. to 800 m. The calibre of his bullets varied from 5.8 mm. to 16 mm. in diameter. The different projectiles varied in weight from 1.9 gr. to 23.6 gr. Both their volume and specific gravity were taken into account. The hardness of his bullets varied from steel to wax; he used rifles as well as smooth-bore guns. Lastly, the greatest variety of material was used to serve in the place of targets.

Glass plates. — Glass plates represent the brittle tissues and much useful knowledge has been derived from shooting through these with different velocities and projectiles. Kocher's plates had a thickness of 3 mm. and were 30 cm.^{2} and encased in a wooden frame being suspended from above.

Firing at such plates with a bullet moving at the rate of 25 m. per second we obtain a defect in them, consisting in an irregular hole, larger than the diameter of the bullet and, radiating from this irregular opening, we notice several long and straight fissures, reaching the periphery of the plate. Bullets with a velocity from 250 to 400 m. show that the effect produced in the plate becomes more concentrated towards the point struck. The fissures are finer, more numerous and shorter, *not* extending to the periphery of

the plate. With velocities varying from 400 to 600 m., we obtain still more intensified central defects. Instead of a large irregular opening, the defect is a small round hole approaching in diameter that of the bullets; the short and straight cracks radiating from the hole are very fine and numerous; at some distance from the central defect are seen circular, branching, intercommunicating cracks; all the cracks seem filled with powdered glass.

These effects, produced by bullets moving with different velocities, occur so regularly that the velocity share in the vi al force of a bullet is shown to be by far the most important factor in their production. A 10 mm. lead bullet and a 7.5 mm. steel bullet, moving alike with a velocity of 595 m., produce like effects. It is interesting to note that the plates themselves, when shot at with these enormous velocities, scarcely move at all.

Tin cans filled with marbles. — In solid and, more especially, the brittle class of bodies, the cohesion among the small particles to be overcome requires a greater force than is the case with fluids, but when their equilibrium has once been disturbed, it remains disturbed, while in the case of fluids the injury is quickly repaired. In order, nevertheless, to illustrate his conception of the perfect analogy existing between explosive effect in fluids by certain velocities, Kocher experimented with tin cans filled with marbles in which, as will be readily seen, the solid particles were given a greater play of mobility upon each other than they had, for instance, in a solid block of stone.

Experiments with such cans show that velocities up to 250 m. are attended by effects marked principally in the line of flight of the bullet. Both entrance and exit openings are nearly alike in shape and extent. With increasing velocities, the lateral or explosive effects are beautifully brought out by the appearance of small humps on the surface of the cans; these are, first, noted about the exit, next, on the sides and, at last, with the highest velocities, in all directions. An exactly similar process occurs in water or in organs saturated with it under the same conditions. That small particles of melted lead from soft metal bullets have nothing whatever to do with the production of this effect, nor that their rotation affects these results very materially is proven by the circumstance that hard bullets fired from smooth-bore guns produce identical effects, providing they possessed the required velocity. The gall-stone-like flattenings on the marbles show the pressure exerted by one upon the other within the can.[2]

Sandstone blocks. — These were 9.6 cm. thick and 30 cm. square. On account of the great firmness of these plates, all the shots show a quicker exh·ustion of both the penetrating and lateral or explosive force of the bullets used. Here the specific gravity of the bullet shows the value of its share in the vital energy. Lead has a more powerful effect than copper; copper a more powerful one than hollow tin filled with wood. Some of the plates are not perforated, but they show that a large, irregularly round plate of stone in the rear has been broken off. This injury being much larger than that in front of the plate, it shows the possibility of the transmission, in a funnel-shaped direction towards the exit, of the force of a bullet, without breaking the continuity of the object hit.

Iron plates. — These were 1 cm. in thickness. The experiments on iron plates serve the double purpose of showing the effects of the bullets on the plates and the reciprocal effects of the plates on the bullets under different conditions. Leaden bullets, for example, when fired into water, soap or wood, show as yet no deformity with velocities of 75 to 150 m. When sent against iron plates, at the same rate of speed, they experience considerable deformity. None of the bullets produces an impression up to 200 m. velocity. With a velocity of 435 m., a lead bullet produces an impression and leaves a whitish, star-shaped deposit, extending for several cm. around it. The bullet itself is mashed into a cake of 5 cm. in diameter, its posterior end alone having preserved its shape, being seen in the centre of the cake. An aluminium bullet, with the same velocity, produces no impression, leaving only a whitish deposit. These shots, then, would illustrate the dependence of the penetrative power of bullets upon the specific gravity of the latter, for, in spite of the velocity being the same, lead and copper will produce deep impressions, while the lighter aluminium only leaves a whitish deposit with a very shallow mark. That, however, the velocity also has a large share in the penetrating power is shown in the difference of the effects on iron plates produced by velocities of 200 m. and 435 m.

In substances like iron, therefore, in which the explosive effect does not occur, the penetrative power of a bullet is shown to be directly proportional to the two component parts of its vital energy ($m.v^2$) and inversely proportional to its volume. Anything, moreover, which diminishes the consistency of a bullet will also diminish its penetrating power.

Lead plates are 3.5 cm. thick and 30 cm. square. A 10 mm. lead bullet, sent against such a plate with a striking velocity of 435 m., gives rise to a cup-shaped depression, 3 cm. wide and 3.3 cm. deep, with a rim thrown up around the entrance, 2.5 cm. high and indented star fashion. A copper bullet of the same velocity completely penetrates the plate, entrance opening 2.2 cm. wide, exit opening 1.3 cm. wide; front rim 13. mm. rear rim 4. mm. high. A tin bullet with wooden filling of the same velocity as the preceding produces a depression 2.2 cm. wide, 2 cm. deep, with a rim 3 mm. high. The projectile is seen at the bottom of the cup-shaped depression, with the wooden filling partly forced out by a core of lead from plate entering in front. An aluminium bullet, same velocity, gives rise to a round impression, 2. cm. wide, 12 mm. deep, rim 1.5 mm. high.

Both soft and hard lead bullets, as well as steel- and copper-jacketed bullets, remain in the target with velocities of 150 m., producing, at the same time, hardly any lateral effect. With velocities of 400 m., those with steel jackets penetrate, and the rest nearly but not quite; while with velocities of 500 m., every bullet perforates the plate.

These shots on lead plates would, therefore, serve to show very clearly that the penetrative power of a bullet is primarily dependent on its velocity, next upon its specific gravity and, thirdly, upon its hardness or consistency. The same may be said of the amount of lateral or explosive effect, for it is seen that the

[2] See the Journal of the Boston Society of Medical Sciences, January, 1899.

diameter of the various openings in the plates is, in every instance, greater the greater the velocity. Notwithstanding, therefore, the undoubted influence of the calibre, the specific gravity and the consistency as well as the rotation of the bullet, its velocity dominates in the production of the characters of the resulting injury.

By the earlier experimenters it was held that lateral or explosive effect could not be produced by a non-deformable bullet with any velocity. The funnel-shaped injury produced by these bullets, now known to be the second degree of explosive action, and in which the exit is wider than the entrance, was explained by them as being due to the rotation of the bullet. It was assumed that melted particles of lead from the projectile, together with parts of the target, were thrown into a whirl by the rotating bullet, these particles acting as secondary missiles and transmitting their energy in an ever-extending circle to the parts directly in front of them, and, in this manner, giving rise to the funnel-shaped defect. This explanation, no matter how alluring it may seem, became untenable after Kocher had produced this identical defect with hard, non-melting and non-deformable bullets, fired from smooth-bore guns.

Kocher's explanation of the nature and production of the lateral or explosive effect is, that the energy of the bullet is transmitted from the parts struck, first, in the direction of the line of fire; next, with increasing velocities, in a funnel-shaped direction towards the exit, and, lastly, with still greater and the greatest velocities, in all directions.

The lead plates, especially, show this effect so well, and prove the correctness of Kocher's explanation, because the action of the bullets on them is preserved in the form of a cast. Our own experiments on glass plates, lead plates, and tin cans filled with marbles have fully confirmed Kocher's views.

Soap plates. — These were 10 cm. thick, 60 cm.,[2] and consisted of the common rosin soap. Bullets with velocities of 150 m. produced effects corresponding to the diameter of the projectiles used; with velocities of 300 m., funnel-shaped canals, 1 cm. in diameter, were produced; with velocities of 435 m., the canals became 2 cm. wide; with 600 m., the openings show a width of 4 cm., and deformable bullets with 600 m. velocity give openings of 9 cm. in diameter.

In these plates, therefore, the gradual increase in lateral effect with increasing velocities is well shown. Up to velocities of 250 m., soft lead bullets remain as yet undeformed; with velocities of 435 m., they lose one-half their length. Hard lead bullets lose one-fourth their length with 435 m. and with 595 m. of velocity, the very posterior end alone remains in shape.

The plates show, among other things, that the resistance offered by the target, no matter what may be its composition, increases as does the velocity of the bullet. When compared with the lead plates, the soap blocks show more delicate shades of difference as regards both the effects of different velocities as well as of the varying specific gravity of the projectiles used.

Tin vessels filled with water or substances saturated with it. — Bullets fired into tin cans that are filled with dry cotton, dry meat or sawdust give, with all velocities, entrances corresponding in shape and diameter to those of the bullet and exits about twice that size. When these substances are wet or the meat is fresh and succulent, then the exits become from four to five times larger than the entrances. With the highest velocities, the cans are torn open and fissured around the entrances.

With velocities from 410 m. or upwards all the vessels filled with water are rent apart and this hydraulic or hydrodynamic effect is made apparent whether these vessels are open or closed at the top. It is, therefore, not necessary, for the production of hydraulic effect, that the water be enclosed within rigid and unyielding walls. It is simply and most strikingly evident that the effect is due principally to the suddenness of the entrance of the bullet which leaves the water no time for making its escape in any direction, not even that of least resistance, but which tends to force it in all directions, like an explosion. It would seem as if the explosive energy of the ammunition that sent the bullet into the centre of the can had been translated into the can and suddenly transmitted to the water contained in it. Round bullets, fired from smooth-bore guns, produce identical effects with the same velocities as do rifle bullets.

Experiments with a water box. — In order to still further illustrate the hydraulic action of bullets in some organs of the human body, Kocher experimented with a water box. As regards hydraulic action, Busch was the first to suggest the idea that some of the effects produced by projectiles in some tissues or organs of the human body might possibly be explained on principles of hydraulic pressure. After him, Küster, Heppner and Garfinkel confirmed this idea and Kocher raised this hydraulic pressure theory to the dignity and importance of a law, true for all tissues of the body containing fluids. Later on, Reger, Bruns and Kikuzi did much to confirm and extend the experiments of the earlier authors.

Kocher had a box made, 345 cm. long, 56 cm. broad, 61 cm. high, open at the top and filled with water to a height from the bottom of 55 cm. Through the side of one end a hole was cut and this was covered in by leather of the kind used in making drum-heads. This was kept in position by an iron frame fitting the opening, and through it the bullets were fired into the water in the box with varying velocities.

Three important results were brought out from these experiments, namely: (1) The dependence of the penetrating power of any bullet upon its velocity; (2) upon its specific gravity; (3) upon its form and deformability. I will here only cite a few examples: A copper bullet, 410 m. velocity, 34 cm. beneath the surface, advanced 256 cm.; a soft lead bullet, 410 m. velocity, 32 cm. beneath the surface, advanced 110 cm.; a hard lead-bullet, 410 m. velocity, 33 cm. beneath the surface, advanced 285 cm.; a soft lead bullet, 250 m. velocity, 29 cm. beneath the surface, advanced 230 cm. under water.

It will be seen, therefore, with leaden bullets, that the amount of penetration is not directly proportional to the velocity, as is the case with hard and non-deformable bullets. Lead occupies an exceptional position in that it shows greater penetration with lower than it does with higher velocities.

When, moreover, leaden bullets are given velocities above 250 m., they will undergo deformity; a lead bullet, 25 mm. long, when sent into the water box with a velocity of 250 m. remains undeformed, while a velocity of 410 m. will cause it to become

shortened to 14 mm. Knowing that the penetrating power of a projectile is inversely proportional to its cross-sectional area, it is almost certainly proven that the lessened penetration, noted above, is entirely due to the deformity which lead bullets undergo when striking the water in the box. That the deformity in this case is due to mechanical force and that, for instance, melting has nothing whatever to do with it, is proven by the facts (1) that mechanical force can produce the same degree of deformity, and (2) that metals with a much lower melting point than lead when fired into water with the same velocity remain solid.

A passing lead bullet evidently creates its own resistance in the water. The higher the velocity, the greater this resistance. From the moment the resistance reaches a point so as to cause deformity, which is at about the velocity of 250 m., explosive effect also becomes apparent. From that time on this effect is increased with the velocities used and at last it results in the bursting of the box and in the water spurting up to the height of 10 feet.

Based upon the results of these experiments and those on tin vessels filled with water, the conclusion seems unavoidable, namely: That the destructive effects of our modern high velocity bullets upon organs containing a large percentage amount of fluid are produced by hydraulic pressure.

That velocity has a preponderating influence upon the production of these effects was also shown by Salzmann (Kocher), who made use of bullets rolled out of filter paper in which "m," therefore, was as much as possible, eliminated. With such bullets Salzmann obtained explosive effects in skulls and, with the highest velocities, he was able to cause their complete destruction. The epiphyses of oxen at close range were completely exploded and, at 21 cm. from the muzzle, perforated. "Expansile effect" (Treves) does not seem a good substitute for the old time-honored name of "explosion."

Both Salzmann and Kocher agree in that the existence of an enclosing capsule is not a necessary condition for the production of explosive effect from hydraulic pressure and, while admitting that deformed and deformable bullets will increase the degree of the effect, the primary and principal cause of it is the velocity of a bullet. The principal reason why it has seemed so difficult at first to attribute to different causes the explosive effects in dry and wet substances is because the effects are not so much in evidence in fluids as they are in solids. The parts of a liquid after a moment come together again, while bone splinters, for instance, will remain splinters.

Measurement of explosive effect. — Nothing, certainly, could be better calculated to show the nature of explosive effect than the experiments of actual measurements by Kocher. Before, therefore, proceeding to study the effects of bullets on human tissues and organs, let us see what we can learn from the experiments made to measure the power of this all-important explosive effect. Two methods have been employed to this end. The one consists in direct manometrical measurement and the other in ascertaining the loss in velocity experienced by a bullet while penetrating its aim.

Table C (Kocher) shows loss of velocity in metres per second by a projectile after passing a 10 cm. layer of water enclosed within a pig's bladder.

TABLE C.

Projectile.	Calibre.	Original velocity.	Loss.
Hard lead	7.5 mm.	599 m.	190 m.
Copper jacket	7.5 "	595 "	57 "
Lorenz steel jacket	7.5 "	578 "	23 "
Hard lead	7.5 "	425 "	33 "
Copper jacket	7.5 "	425 "	30 "
Lorenz steel jacket	7.5 "	425 "	7 "
Hard lead	10.0 "	425 "	74 "
Soft lead	10.0 "	428 "	117 "
Copper	10.0 "	425 "	14 "
Copper	round	425 "	64 "

The above table shows the enormous difference in the loss of velocity experienced by a large-calibre or a deformable small-calibre bullet, as compared to a small or non-deformable large-calibre bullet. It also shows the relatively greater loss of velocity with the higher than with the lower velocities for all bullets.

Table D (Kocher) shows the loss in velocity of a 10 mm. hard lead bullet after passing through the extremities of a human cadaver. Striking velocity = 420 m.

TABLE D.

Parts.	Loss in metres.
1. Upper arm	79
2. " "	60
3. Forearm	58
4. "	93
5. Thigh	139
6. Leg	183
7. Thigh muscles	124
8. " bone	175
9. Leg bones	123

The above experiments show that projectiles of different composition, and of which it has long since been known that they possessed different degrees of penetrative power, also experience different losses in velocity during their passage through certain aims. Generally speaking, this loss in velocity is inversely proportional to the hardness of the material of which the bullets are made and directly proportional to their calibre.

The Lorenz projectile, with its non-deformable steel jacket, loses the least amount in velocity, the Rubin projectile with its strong copper jacket comes next, and the hard lead projectile next, the soft lead last. By far the greater part of this loss in velocity is converted into lateral or explosive effect, because the loss in the total power of the bullet in becoming deformed is but a few kilogrammetres, amounting, as it does, in the case of a 10 mm. Vetterli to only 6 or 7 kgm.

With a velocity of 410 m. a 10 mm. Vetterli strikes its aim with a force equal to 181.6 kgm. While penetrating the muscles of the thigh, it loses 92.6 kgm. or very nearly one-half of its original power, by a reduction of its velocity from 410 to 300 m. In passing through the bones of the lower extremity, it loses 113 kgm., which greatly exceeds the amount of mechanical force necessary to cause its deformity, and which is only 10 kgm. It demonstrates the fact that the largest share of the original power of the bullet was converted into lateral or explosive effect, in this instance, at least twice as much as was necessary to cause its deformity and penetration together. From the fact that a bullet loses more of its force in passing through the lower than it does in passing through the upper extremity, we must, very naturally, expect the former to result in a more serious injury than the latter.

A knowledge of the losses in velocity of certain bullets through the different parts of the human body would enable the surgeon in the field to estimate the range of lodged bullets, providing the bullets did not

happen to be badly deformed. We know, for example, that a 7.5 mm. bullet, with an initial velocity of 600 m., has a remaining velocity of 170 m. at 2,000 yards' distance from the muzzle. Supposing that it should, at that distance, enter the outer side of one thigh and go only through the fleshy part, thus losing 124 m. of this remaining 170 m.; supposing, further, that it now enters the other thigh in a direction towards the bone, with the remaining 46 m. of velocity, it would be bound to lodge in the femur of the second thigh. Such calculations would, in my opinion, come much nearer the actual range at which the fire was delivered than the best guess.

The second method of determining the amount of lateral effect consists in direct manometrical measurement. Reger was the first to employ this method, but Kocher, by devising a very ingenious piece of apparatus, obtained thereby much more accurate and reliable results than Reger. This is schematically represented in Fig. 1.

Legend. — Shows the lower part of a tin vessel filled with water. Into the bottom is fitted the cylindrical projection of the iron stand, within which slides a cylindrical piece of steel resting on a lead bullet. This may be fitted to the sides, top or bottom. When a shot is fired through the vessel the power exerted upon the water will cause the projectile to become shorter by direct compression. The mechanical power necessary to do this may be easily ascertained and expressed in kilogrammetres. By means of this piece of apparatus, Kocher was able to calculate the amount of lateral pressure caused by a 10 mm. Vetterli, 25 mm. long, entering a tin can filled with water and which amounted to a little over 23 kgm. per square centimetre of surface. By means of the same instrument, it was, moreover, clearly shown that hard lead bullets gave considerably less pressure than soft ones; more pressure was also produced when the projectile passed nearer to the measuring instrument than farther away from it, but regardless of whether the vessel itself was open or closed (see next table). While, therefore, the pressure may rise to a higher degree, when the water is enclosed within resisting walls, the effect itself occurs without such walls.

TABLE E (Kocher).

Bullets.	Calibre.	Velocity.	Atmospheric pressure per cm.²	
			Sides.	Bottom.
1. Soft lead	10 mm.	435 m.	37.5	37
2. Hard lead	7.5 "	595 "	42.5	41.5
3. Copper jacket	7.5 "	595 "	20	22
4. Lorenz steel jacket	7.5 "	595 "	21.5	24

Some experiments also were made with a hollow iron shot, into which holes were bored for the entrances and exits of bullets. These holes were closed with bladder skin and the shot filled with water, of which it held 1½ litres. The result of shooting through it, under these conditions, was the bursting of the shell into fragments. Experiments with skulls, with the same apparatus attached, gave a lateral pressure of 10 atmospheres.

The analogy in the effects of bullets produced on tin cans containing water on the one hand, and on tin cans filled with marbles on the other hand, is that in both the water and the marbles are suddenly dispersed in all directions by the passing bullet when the latter has the required velocity. As the velocities increase from the lowest to the highest, we first notice only an effect in the direction of the shot, next by a funnel-shaped exit, and, at last, the effect shows itself in all directions, as is evidenced by the bursting of the can of water and the impressions of the marbles on the surface.

The very highest degree of this effect, and which presupposes the existence of rigid walls, is hydraulic pressure. But to this condition neither the skull, with its content of brain, nor the cylindrical bones, with their marrow, exactly correspond. The hydrodynamic effect noted to occur in these is not the same in degree but only in kind.

Finally, since it is well known that water offers less resistance than does, for instance, the cortical substance of bone, we must expect that explosive effect in the latter will continue to occur with lower velocities and longer ranges than it does in water-containing tissues or organs. The effect itself, however, once produced, will reach a higher degree in water and water-containing tissues than it does in bones.

Human tissues and organs. — For the purpose of a better appreciation of the characters of gunshot injuries in the human body, we will do well to study such injuries on the different tissues separately. To this end, we may, with Kocher, divide them into three categories or classes: (1) The brittle; (2) those that contain fluids, and (3) the elastic tissues.

The brittle tissues. — The cortical substance of bone is the only tissue in the human body belonging to this class, and the more this preponderates over the other in any part, the more lateral effect in all its forms may be expected to occur in that part. The reduction in the calibre of bullets and the hard metallic jacket have resulted in reducing the size of skin wounds and limited the occurrence of hydraulic effect in the soft parts to shots at close range. The injuries to bones, on the other hand, continue to be serious. Special attention has been called by von Coler and Schjerning to the small skin wounds that are found over very serious bone injuries, particularly the long cylindrical bones. To one acquainted with experimental literature, it ought, therefore, give no surprise to find small skin wounds in the field even behind perforated bone. Nor would he allow himself to be misled by these small skin wounds as regards the possible existence of more serious injury to the bones underneath. That this has, however, actually occurred, we are led to infer from what Dent says with regard to these small wounds. He says: "A feature of small-bore wounds was the large amount of callus afterwards thrown out and, therefore, a neighboring joint might become fixed." The fissures existing in the bone underneath a small wound of exit are not so much in evidence in the field nor can they be brought out as clearly as a dissection on a cadaver can bring them to light in a laboratory. While, therefore, a surgeon not personally acquainted with experiments might be surprised at this abundance of callus which is thrown out, one who has such an acquaintance would, on the contrary, be led to look and prepare for such occurrences.

A careful comparison of the results obtained by experiment have, moreover, brought very prominently into notice slight differences in hardness, elasticity and percentage amount of moisture between different bones as well as different parts of the same bone. Hence, also, it has become clear that injuries produced under apparently identical conditions may still differ somewhat in character. Thus, for instance, the relative

proportions of hard, bony substance to the volume of the cavities within have been studied and calculated by Habart and Friedrich (Kocher). In the femur of a young man the proportions of solid substance to volume were found to be 1 : 1.26; in the tibia, 1 : 1.6. In the femur of an old man the proportions were 1 : 2.11 and in the tibia 1 : 2.45. In a humerus, 32 cm. long, Habart found the marrow cavity 21 cm. long and 13 mm. at its greatest breadth. The closed spongy ends measured 7 cm. above and 4 cm. below. The thickness of the cortical layer in the middle was 5 mm.; 4 cm. above the lower end it was 3 mm. thick, and where it passes over into the articular cartilage it was only 1 mm. thick. The cortical layer of bone is, as a rule, slightly thicker in front than behind.

In view of the existence of these differences and the effect which these will exert on the production of injuries, it seems at once but reasonable to demand that they shall be taken into account whenever bone injuries either in the living or the dead are compared. Observing these points, Kocher, for instance, was unable to detect any differences between the injuries produced at long distances and such as were produced with reduced ammunition but by the same velocity at close range.

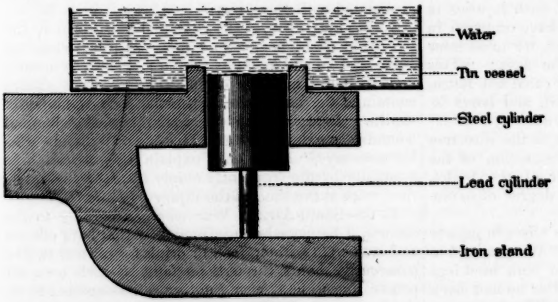

Fig. 1.

It is a well established fact that the lateral effect becomes greater the greater the resistance which a bullet has to overcome. As a solid body, therefore, bone must show signs of lateral effect with lower velocities, in other words, at greater distances than other tissues do. This same effect must, moreover, be greater the nearer we get to the middle of the diaphyses of cylindrical bones and to certain borders that are especially strengthened by extra layers of compact bone, such as we find about the linea aspera of the femur.

In view of the varying composition of different parts of the same bone, it is, moreover, easily understood how opinions could differ as widely as they did with regard to bone injuries in general. Since now, however, a distinction has been drawn between injuries to diaphyses, metaphyses and epiphyses, these differences of opinion have become reconciled.

The type of a gunshot fracture is today, as it was formerly, a fracture with splinters. Transversal and parallel longitudinal fractures are the result of bullets of low velocity in which the parts are simply pressed apart or bent and the walls pushed in. When, therefore, Mr. Treves says: "With regard to the alleged obliquity of fractures I should say deliberately that the great majority of fractures in this war due to Mauser bullets have been transverse,"[3] he gives the best possible and most unavoidable proof that the majority of fractures that came under his observation were produced at long range. The general rule is that the greater the distance or the lower the rate of velocity of a bullet producing a bone injury, the longer and the less numerous will be the splinters of the resulting fracture and the more likely it is that the splinters will remain in position and adherent to the periosteum; the bone may be perforated and yet show only long fissures running parallel to its long axis, as experiments have shown. The closer the range the smaller and the more numerous will the splinters be and the more perfect their separation from the periosteum as well as from each other. Fractures in which the splinters are small, fine and numerous and in which the exit is a large cavity filled with bone sand, driven into the neighboring and pulped muscles, may be produced experimentally at 100 m. distance. That Mr. Treves[4] has seen some fractures that were produced at close range, we must infer when he says: "I have seen a fracture of the humerus in which the bone was broken into twenty-three small fragments,"[5] and, also, when he gives an account of a case in which the bullet had entered the epiphysis of the humerus and blown off its head, he says: "On examination, hardly any fragments of bone were found at all, they had been practically pulverized." This is a very lucid description of an explosive injury as it occurs in an epiphysis.

But even in such extensive bone injuries, it is not at all uncommon to find both entrance and exit exceedingly small. In an experimental injury of this kind on a knee joint, I found both exit and entrance wounds small, not exceeding the diameter of the bullet, but dissection revealed complete comminution of the articular end of the tibia, the capsule of the joint filled to distention with bone sand. The copper jacket of the bullet was discovered in the centre of the mass of detritus, the lead core, afterwards found on the floor, had alone escaped through the skin, causing a very small skin wound.

Between these two extremes we find the typical fracture first described by Bornhaupt and called by him a butterfly-fracture, occurring in long bones about the diaphysis. In this fracture, two triangular pieces of bone seem broken out on either side of the point of perforation. The apices of the triangles are at this point, while the hypothenuses are at the periphery of the bone. Behind is found a longitudinal fissure dividing the two fragments into two lateral halves. The evidence seems conclusive that the tubular character has everything to do with the production of this very characteristic fracture with certain velocities, because Bornhaupt has produced similar fractures in cylindrical glass tubes.

Mr. Treves,[6] speaking of bone injuries, says, "The following four statements are not borne out by experience in the present war. The first is that the severity of the injury to bone decreases as the range increases; the second is that explosive effects are produced when a bone is hit at short range, such as 500 yards or under; the third is that fractures are nearly always oblique, and the fourth is that when a bone is fractured, the exit wound is always larger than when this does not occur."

From what has already been said with regard to injuries to diaphyses and from what we will hear presently with regard to injuries to epiphyses, the above cited four textbook statements do not perhaps go far enough to convey the full impression of their meaning, but as far as they do go, they nevertheless appear to be not so far from being correct as Mr. Treves would have us believe.

Tissues containing fluids. (*a*) *Muscle.* — In muscular substance, explosive effect has reached its minimum degree of intensity. Bruns obtained clean perforative injuries at distances of 120 m. The canal was not larger than the diameter of the bullet and its adjoining walls were practically uninjured. Von Coler and Schjerning also obtained such injuries in near shots. That such injuries also have occurred in the field and at much larger distances, we must infer from what Sir William MacCormac says: "This slender, elongated bullet produces a canal not much, if anything, larger than a goose quill, and bores its way through, as if the hole had been done by a drill." Nevertheless, a defect in the muscles, in the direction of the bullet, attended by a total destruction of the parts to the extent of the diameter of the bullet, marks, according to Kocher, the first degree of explosive action.

At a distance of 30 m. explosive effect in muscle becomes very much more apparent. We obtained in a young ox an injury which involved both hind legs at that distance, about two minutes after he had been killed by a shot through the brain. The bullet entered the fleshy part of the left leg, midway between ankle and knee, and passed out through the right leg of the opposite side about the same point. The first entrance and the second exit wounds were not much larger than the calibre of the bullet, while the first exit and the second entrance wounds were of the size of a silver dollar. The wounds might be represented by two funnels, their wide ends turned towards each other, on the inside of the legs.

Shots through muscle, at greater distances than the above, result in canals that are smaller even than the calibre of the bullets, but the above example shows that hydrostatic pressure may be produced, even in muscle, by a simple increase in the velocity. It begins to show itself by a funnel-shaped exit and ends by a pulping of the tissue adjoining the track of the bullet. Mr. H. Temple Mursell,[7] civil surgeon attached to the British forces in South Africa, with regard to this point, says: "It has been frequently stated that the damage to the tissues inflicted by a small hard cased bullet, such as the Mauser, is comparatively small and, within certain limits, the statement appears to be correct. . . . In those instances in which it has been necessary from any cause to follow up the track of such a bullet wound, the death of the tissue around the track has been found to be much in excess of what might be anticipated. The resulting cylindrical cicatrix is of considerable extent and often produces more crippling than would be expected, owing to the muscles and their sheaths becoming firmly bound down." Such statements, based upon experience in the field and confirmatory of the experiments in the laboratory, might be multiplied. They would tend to make us slow and careful before pronouncing an opinion as to the benignity of an injury, because of the presence of small entrance and exit wounds. We must wait for more remote consequences. Many of those wounded in the war in Cuba, and whose wounds were considered trivial at the time, have since been invalided from the service.

It has, moreover, been observed by Reger that, while in one muscle we obtain as yet clean perforations, in another, containing slightly more fluid, we already obtain a beginning explosive action, the velocity being the same in both cases. Muscles of different animals as well as different muscles from the same animal behave differently in this respect, and hence also the clash between the opinions of the earlier experimenters and of those in the field not thoroughly acquainted with these facts.

In the heart, liver, intestines and the bladder, the hydraulic effect begins to appear with velocities of about 250 m. and amounts to more or less, in accordance with the quantity of fluids which these tissues contain at the time, as experiments have abundantly shown. As regards the benign character of abdominal wounds occurring in South Africa, Sir William MacCormac says, "I can only explain this considerable immunity by the frequently empty state of the intestinal tract at the time of the injury" (*Lancet*).

In the South-African War where, according to the reports, it happened not infrequently that both officers and men went without food or drink for ten and twelve consecutive hours through no fault of their own, all penetrating wounds would naturally be expected to be smaller, except those in the cortical portions of bone. This state of things was therefore not an unqualified evil, but rather a "blessing in disguise."

(*b*) *Spongy bone.* — In the diaphyses we have found an almost complete absence of hydraulic effect, which, in epiphyses and metaphyses, becomes the prominent feature. Hydraulic action commences to show itself in spongy portions of bone with velocities of 300 m. The spongy substance is ground up into sand, the cortical layer is splintered and these splinters are driven in all directions under the highest velocities. Hence, also, the difference in the injuries between hard cortical and spongy epiphyseal bone and the necessity for a separate classification. It will, therefore, not do in the future to speak simply of bone injuries in *military* surgery, without specifying the parts of the bone in which these injuries were produced.

Busch (Kocher) has shown that the amount of destruction experienced by any part of a bone depends primarily upon the amount of resistance which it opposes to a bullet. This resistance is less in spongy than in hard bones. When, therefore, von Coler and Schjerning noted the occurrence of rather serious bone injuries at unusually great distances, while Reger and Bruns found them so slight as to call them benign and the bullets that produced them humane, the former experimenters referred to hard bone and the latter to injuries as they occurred in spongy bone.

[6] British Medical Journal, January 27, 1900.
[7] Lancet, January 23, 1900.

(*c*) *Metaphyses.* — According to Kocher, it was first proposed in 1871 that the portion of bone lying midway between the epiphysis and the diaphysis of a long cylindrical bone should receive a separate name and its injuries treated under a separate head. The term "intermediary" bone was applied to it by German surgeons. Kocher proposed the name of "metaphysis," which seems to have been accepted. In this portion of bone, the cortical layers begin to become thinner than they are in the diaphyseal portion, while the spongy substance, at the same time, shows an increase. Hydraulic effect prevailing in the epiphyses, fractures with splinters about the diaphyses, injuries to metaphyses, must share the characters of either. Injuries to metaphyses are, as a rule, more serious than those of epiphyses and less so than those of diaphyses.

(*d*) *Flat bones.* — In flat bones, simple perforations seem to be the rule. Injuries to flat bones are serious only in direct proportion to the importance of the organs which they protect. The highest velocity shots upon skulls, filled with brain, show that they are attended by a high degree of explosive or hydraulic action. Any one having once fired a full velocity bullet at such a skull and seen the fragments of the skull fly apart, the brain scattered to the winds, will probably not again speak of "expansile effects," but will call the event a plain explosion. Empty skulls will give clean perforations and low velocities, irregular openings.

The elastic tissues. — Whenever we shoot into elastic material, such, for instance, as is represented by a soft, flexible rubber plate 3 cm. thick, we obtain a very uniform series of defects; mere conical perforations with the highest velocities and straight and very narrow canals with the lowest. The parts are shoved aside with such ease that a projectile of even the highest velocity at present attainable does not push the parts hit directly in front of it, but only shoves them aside temporarily. These uniform injuries cease to occur from the moment we substitute an inferior quality of rubber, so much so that the quality of rubber may be tested by a shot.

This circumstance has a practical bearing, for it is well known that by no means all the so-called elastic tissues of the body contain the same amount of elastic material, and in accordance with this difference, their injuries must differ just as do those of elastic rubber plates of different quality. Some elastic tissues, moreover, like the skin and the blood vessels, part much more easily in one direction than in another. Hence, we often get either transverse or longitudinal rents or fissures instead of clean perforations. In skin wounds on fresh cadavers, for instance, the elasticity of the skin becomes apparent only at the exit, because about the entrance it is backed by a less resilient tissue. Sometimes, also, but only with the lowest velocities, we obtain slit-like entrances which occur more often with the exits. With slightly higher velocities the entrance wounds become round. When, however, an elastic tissue is distended so as to neutralize its elastic nature in certain directions, we get perforative effects with loss of substance. This also occurs in situations where elastic tissue is adherent to non-elastic membranes.

Under such conditions the defect produced by a bullet in the skin, for instance, or the fascia, is of the form of that of the tissue directly underneath it: A round hole when over muscle; a longitudinal slit when over bone. When the injury has occurred in the neighborhood of tissues liable to show explosive effect, the skin partakes of the character of the injury done to those tissues. It is in this manner that we get the fissures and rents, shaped like an H or like a star, also the long tears in serous membranes and those covering the liver.

Nerves as well as blood vessels show sometimes a miraculous escape from injury even with the new bullet, but only with the lowest velocity; with the higher velocities, they are simply perforated and portions of their coats scooped out; the ordinary injury, however, is a transverse or longitudinal rent similar to that found in the skin.

Shots through lung tissue, especially when in a distended state, show a complete absence of lateral effect even with the very highest velocities, providing the bullet entered undeformed.

Experience in war. — We have seen from the preceding experimental evidence that the human body, from the point of view of the military surgeon, must be considered as a compound body, made up of a variety of tissues, each of which reacts differently upon a passing bullet. It is for these all-sufficient reasons that the original division of the trajectory of a bullet, with reference to the injuries to the human body, into three zones has been given up by experimenters years ago. Recent experience, also, would indicate that the injuries occurring in the field either are severe enough to cause immediate death, or promise a fair chance of recovery on account of their being rather light. Injuries in general, consequently, would naturally fall into two great groups, the severe and the light, and since the former occur at close range and the latter at long range, we now would more correctly speak of near-shots and far-shots (*Nahschüsse* and *Fernschüsse*).

Indeed, when we read carefully the descriptions given by military surgeons of the injuries which came under their treatment and observation in recent campaigns, we can hardly escape the conclusion that by far the greatest number of them were light. La Garde ("Remarks upon Gunshot Wounds") says that he only saw one case in Cuba that approached anything like explosive effects. This great scarcity of the severer class of injuries can only be due to the fact that engagements occurred at distances that made their occurrence impossible, while those that actually did occur were so severe that the men remained where they dropped and were buried out of sight long before the surgeons had time to notice them.

In any attempt, therefore, at discussing the injuries produced under the more exact conditions of experiment with those that occurred in the field, a comparison between the ranges would be of the first and greatest importance. It is here, also, that we meet with our first great difficulty, for it is easily seen, while the range in a shooting-gallery or laboratory can be measured with absolute accuracy, that in the field, in the majority of cases, must remain practically unknown. There is no guess, however good, no range-finder, whatever its construction, that can approach an actual measurement of distance, or of the velocity of a bullet.

As regards South Africa, for instance, Mr. Charles A. Court, in the *Nineteenth Century* for November, 1900, page 712, says: "Until all ranks became ac-

customed to the clearness of the atmosphere, ranges were frequently underestimated by one-half the real distance. . . . The Boers, excellent shots, would open fire at 2,000 yards' range from every scrap of cover that could shelter a man."

Mr. Dent says with regard to range: "Unfortunately reliable information can very seldom be obtained on this point," and Mr. Treves [8] remarks: "The damage done by the Mauser depends mainly on the range." Although an additional four months' experience caused Mr. Treves to change his mind with regard to the influence of range, he has no doubt since then had sufficient leisure to repent and to revert to his former and more correct conclusion.

At any rate, those of us who have seen shots at close range, either due to accident or suicidal intent, and long distance injuries in the field must be pardoned for looking upon the range as having the most important bearing on the character of the wounds produced by bullets. This is indeed so much the case that, even in the absence of more accurate information of field ranges, the trained military surgeon may be trusted to read the range in the character of the wound before him, with at least the same accuracy as any rangefinder can. We may, then, even without an exact knowledge of the field ranges at which bullet wounds are produced, conclude with perfect safety and all scientific reserve that practical experience has fully confirmed the results of experiments in respect to the influence of range. All other conclusions contrary to this would seem to have been arrived at without a knowledge or personal acquaintance with experimental injuries, so necessary for a correct interpretation of the meaning of gunshot injuries on the field.

Our own conclusions would, therefore, exactly coincide with those of La Garde, who says: "From the foregoing I believe we should conclude that the work of the experimenters agrees with the conditions found in war, and that their work was not done in vain."

CLINICAL NOTES AND COMMENTS: DEGENERATIVE DISEASE OF THE SPINAL CORD ASSOCIATED WITH ANEMIA.

BY ROBERT T. EDES, M.D., BOSTON.

THE connection between certain fairly definite spinal symptoms, not usually recognized as belonging to the well-marked system diseases on the one hand, and conditions of malnutrition of the blood on the other, is of much interest both to the neurologist and to the general practitioner.

At first, the cases showing this connection were spoken of as spinal degeneration, dependent upon pernicious anemia, and as the "pernicious" is usually the most severe and persistent form of anemia, the association is certainly a very frequent one. But, on the other hand, since many cases of pernicious anemia progress to a fatal termination without spinal symptoms, and since fairly characteristic symptoms of this spinal type occur in cases which do not exhibit blood appearances diagnostic of the specific form, the association is evidently not necessary even though it be frequent.

The present tendency is to put the anemia more or less into the background, and to speak rather of a toxemia which may be a common cause of both conditions. This toxemia, like many others equally important, is largely hypothetical, and perhaps there is more than one kind, but its existence is rendered very probable by the sequence of the condition spoken of upon quite a number of infectious diseases. These are, according to Dana, influenza, acute infectious diseases, diarrhea and dysentery, possibly shock, lead and malaria, and some others less common and less certain. Strangely enough, syphilis, that arch enemy of the nervous system, is not among them as enumerated by our countryman, but a very elaborate article, by Risien-Russell, Batten and Collier,[1] seems to make up the deficiency, for of their 7 cases 4 had a definite history of syphilis, and in only 2 could it be excluded with comparative certainty. Congenital predisposition does not seem to play an important part, or at any rate it is not easy to demonstrate in persons in or beyond middle life. Dana makes the suggestion, which is highly important, not only from the point of view of etiology but of prognosis and therapeutics, that possibly some of the obscure paralyses of children which recover, as most adults do not, are in reality cases of this kind.

Which set of symptoms has existed first in any given case cannot always be known, inasmuch as both begin gradually, and neither is likely to be looked for before its presence is distinctly announced. It is more likely to be the nervous ones which first attract attention, as the paresthesiæ or the pareses force themselves upon the attention of the patient, while he may not be aware of increasing pallor, or it is referred by himself or his friends to an indefinite condition of health below par.

The early sensory symptoms are numbness in the extremities, inability to use the hands for fine work, and a sense of extreme coldness of the feet, which latter, however, may have a double cause in an actual deficiency of circulation as well as interference with paths of sensation in the cord.

The motor symptoms are of general weakness of motion and co-ordination rather than of distinct paralysis of any group of muscles or special movements. The deep reflexes are at first apt to be exaggerated. Later, everything has progressed and we may have a more or less extensive anesthesia, absolute paralysis, and absence of deep reflexes. The following cases illustrate several of these points:

CASE I. A professional man, aged about forty, who had worked hard and had had diphtheria, after which he lost smell and taste, but had no paralysis. His wife thinks she noticed that he was becoming pale before the onset of the paralytic symptoms. He began to lose control of his legs and fell several times, but kept about on crutches for some months. No severe pain. When first seen by me his appearance would at once have suggested anemia, probably pernicious, at the first glance, as he was fat, extremely pale, with a sort of puffy look that suggested but was not edema. He could draw up his legs and raise his toes. There was distinct loss of tactile sensibility throughout the legs, which on the inside of the thighs and the perineum became almost complete anesthesia. The sense of position was lost. There was no distinct girdle sensation, but pain and soreness about the sacrovertebral junction. He said, when he was sitting up he felt as if the body rested on the pelvis by a ball and socket joint. He could distinguish

[8] British Medical Journal, January 27, 1900.

[1] Brain, Spring, 1900.

heat and cold on his feet and the outer aspect of the legs and thighs. The knee jerks were absent, and were said to have been so for some time. The plantar reflex was normal. The wrist and elbow jerks were normal or perhaps slightly increased. He had not lost control of the rectum or bladder. The respiratory, circulatory and digestive organs were normal. He had a very good appetite; took and digested a very good amount of food.

An error was made in the estimate of blood color, but it was not far from 25%; red corpuscles, 1,760,000. The whites were not increased in proportion to the reds, and they were divided in about the usual proportions, except that the eosiniphiles were a little above the average but not distinctly above the normal. There were no nucleated reds, but the variation in their size and shape was extreme. The patient died about three months after these notes were made, after a few days of rapid failure with a rise of temperature. There was no autopsy, but there can be no doubt of the extensive and extreme degeneration of the lower portion of the cord.

Case II. A man, aged seventy-six, tall and rather pale, had bronchitis (grippe?) in September, since when he had not been well or walked well. In December he had a feeling of numbness in his hands and of numbness and coldness in his feet. His back felt numb. He walked awkwardly and feebly without crutches, but better with them. There was no diminution of sensation anywhere nor any hyperesthesia; heat and cold were well distinguished. The knee jerks were normal or slightly increased, but there was no ankle clonus. The heart and pulse were weak, and he had frequent attacks of syncope. No blood counts were made, but a cover-glass preparation showed nothing characteristic of pernicious anemia. He died in February.

Case III. A man, aged seventy-one, of active habits, had not been well for two years, except during a visit to California the previous winter. He was seen on January 13, 1887. Last September he noticed shortness of breath on exertion, and his feet and legs felt cold. Six weeks before my first visit, on going out into the street, he felt a sudden weakness of the legs and was obliged to return, which he did with much difficulty, being hardly able to get up the doorsteps. When I saw him he was in bed, though he stood up for part of the examination. He complained chiefly of coldness and stiffness of the legs, as well as of weakness, but of no pain. A sense of constriction across the lower part of the bowels was constantly present, and seemed to have little or nothing to do with any condition of constipation or otherwise, nor with any abdominal tumor, although this latter possibility was seriously considered. With the history of the sudden attack and the peculiar sensations and weakness of the legs, attention was at once directed toward spinal disease. The legs could be moved freely in any direction as he lay in bed. The muscles were flabby and small, but not decidedly atrophied, and reacted well to the faradic current. Sensation was everywhere present, and both superficial and deep reflexes were of nearly normal intensity. He could stand with his eyes shut. Examination of the urine, rectum and of the fundus of the eye gave no further information. The blood count was, at first, 1,575,000, and there was very marked poikilocytosis. This was before the days of staining and of differential count, so that my diagnosis of "pernicious" anemia, although it was agreed to, on the basis of a cover-glass preparation, by one of the first authorities in the world, would probably not now be considered justified.

The blood count increased to 2,540,000, coinciding with a considerable gain in flesh and strength, although it was found after some months that the patellar reflex had disappeared without any other symptom of increasing paralysis. In the extremely hot weather of July he contracted an enteritis of which he died.

Case IV. Mrs. M., a patient of Dr. Tanner, of Dorchester, age about fifty-five. A year and a half ago she had "bilious fever," with vomiting, chill and jaundice. During the interval up to the present time she has had at times symptoms similar to those of which she now complains. Day before yesterday she had another chill. She has had numbness of the hands and feet, and now has distress as if her feet were in cold water. She can walk but little, but can make any movement freely. Sensation perfect. Knee jerks normal or perhaps slightly increased. Ankle clonus on the left side. No increased elbow reflexes. No nystagmus, no tremor of the intention kind or otherwise. Her sight was not good, but the precise nature of the trouble was not determined. There was a large white spot in each retina, and on the right side the disk was possibly too white. These appearances were probably due to an old retinitis. The blood was unfortunately not counted or its color per-

centage determined, but a cover-glass preparation was made and examined. This showed no marked departure in quality from the normal which would indicate the presence of any special form of anemia.

The patient made no essential improvement. She had jaundice for some time before her death, which came by way of heart failure, about six weeks after the notes were made.

Autopsy. — The body was quite fat, although it was said that the patient had lost much flesh. The liver was large and the gall bladder distended with bile. It contained a few small black stones, one of which was in the cystic duct. This was undoubtedly the cause of the jaundice present some time before death, and possibly of the previous attack. The kidneys were large and palish, of structure apparently normal to the naked eye. The spleen was large, soft and pulpy. The uterus contained several fibroids. The heart was large, flabby, and with a large amount of fat upon its surface. In places its structure was pale and friable. Under the microscope some of the fibres in the right ventricle and in the septum were nearly destitute of striæ, and showed some fatty granules. There was little or none of this condition in the left ventricle. There was no atheroma of any of the arteries. The muscles in the popliteal space were light colored and friable, and under the microscope showed some fibres with few or no striations and some fine granules (fatty degeneration). The brain was apparently normal to the naked eye, and was not examined further, except the medulla oblongata in its lower

portion. Portions of the spinal cord, the lumbar region and a small piece of the extreme upper cervical just below the oblongata were normal to the naked eye.

Sections made after hardening showed the appearances usually found in this form of disease as indicated by the cribriform condition of the connective tissue or neuroglia, showing large and irregular meshes where the degenerated and swollen nerve fibres have fallen out, and presenting a very marked contrast to the regions still normal, with much finer and uniform meshing. Everywhere, however, there are found considerable numbers of fibres apparently normal. The areas of this degeneration were found in the lower (third and fourth) lumbar region only in the posterior columns, but at the level of the first lumbar nerves there were in addition very distinct patches in the posterolateral columns and in each anterior horn beside the median fissure. In none of these cases except in the anterior horns did the lesion come quite to the surface of cord; and in the posterior columns there was a narrow strip of tissue, at least comparatively normal, along the inner border of the posterior horns. In the upper cervical region where the decussation of the pyramids is not quite complete corresponding areas may be found, but of course more widely separated. In the medulla at the level of the olivaries there are still evident remains of degenerated patches toward the outer posterior border, but so ill defined that it is difficult to localize them more accurately.

It has been remarked of these cases that there is a tendency to formation of focal lesions, that is, that the degeneration does not follow continuously any of the so-called systems of fibres. The gap (a long one) in this specimen makes it impossible to say that such may not be the case here also, but so far as it goes, the degeneration seems to follow very closely the conducting paths of voluntary motion and sensation, and thus corresponds precisely to the symptoms.

As to the gray matter it would not be possible to say, in the absence of the more delicate methods of preparation, which should be applied to very fresh specimens, that the cells were absolutely healthy, but the larger groups in the lumbar region apparently retain the full number of well-developed cell bodies, which show no signs of degeneration. The small blood vessels, those of the membranes, and those within the cord are free from any marked changes.

The literature of this subject includes in this country careful studies by Dana,[3] J. J. Putnam [3] and (with E. W. Taylor),[4] and Lloyd.[5]

Among a large number from foreign literature may be mentioned a very recent and elaborate study by Risien-Russell, Batten and Collier [6] of a series of cases of nearly the same character which, however, present some anatomical distinctions more or less differentiating them from ours. The limits of their group certainly do not exactly coincide with those of the Putnam-Dana type, and the authors are inclined to lay less stress upon the blood changes.

THE DIFFERENTIAL DIAGNOSIS OF INTESTINAL OBSTRUCTION.[1]

BY Z. BOYLSTON ADAMS, M.D., FRAMINGHAM, MASS.

To make a complete "dynoptic picture of the diagnosis," as described by Valleix, would be impossible in intestinal obstruction unless in a volume. The number is legion who have written more or less at length upon this important subject. A study of the symptoms and causes is all that I shall attempt in the present paper.

Among causes we find such things as paresis and nervous inhibition;[2] muscular spasm from straining at stool or the abuse of purgatives, or from extraneous causes such as impaction of the ureter; embolism of the superior mesenteric artery; cancer and sarcoma and tumors of various sorts; gall stones and enteroliths, and the presence of foreign substances, such as hair, magnesia, etc.; ulcers in the bowels; stricture of the rectum; abscesses of various origin, including perityphlitis; hernias, reduced or not, or caused by mesenteric openings or bands of cicatricial tissue; intussusception; volvulus; and lastly tubercular or purulent peritonitis and syphilis. These causes act in three principal methods, namely, by invagination, by pressure or impaction, or by strangulation.

It is idle to insist upon the inadequacy of statistical tables in determining the diagnosis. We may, however, affirm that in a majority of cases, acute or chronic, such as are ordinarily met with, it is possible to find in the previous history or in the clinical observations and local phenomena, by palpation under ether or examination per rectum, a cause, quasi-mechanical, which does not require a differential diagnosis. Some few there are among the many causes mentioned which seem to be doubtful, or are so rare that they may be said to be non-existent.

It must, I think, be admitted that volvulus is rarely, if ever, a cause of fatal obstruction. Dr. Thomas Bryant, the famous London surgeon, in his Harveian Lectures upon this subject does not mention it except to say that it might have been suspected in a certain case which he describes. My old instructor, Dr. J. B. S. Jackson, declared that he had never found volvulus at the autopsy, although not rarely diagnosticated before death.

We have the authority of Gross, Erichson and others for the statement that closure of the bowels by spasm alone, sufficient to prevent the passage of feces and even of air, has been the cause of death. This has been denied by Dr. Frank Hamilton on anatomical grounds, although Dr. Hamilton admits that spasm of the muscular coat of the intestines, with relaxation and dilatation above the spot so contracted, may produce the phenomena of fatal ileus. And this, I believe is usually the case.

Leichtenstern, in "Ziemssen's Cyclopedia," says that without important testimony, objective or derived from the previous history, the diagnosis of constriction cannot be made with certainty, and Rokitansky and other morbid anatomists have shown us that invagination of the intestines may occur without appreciable symptoms to indicate its existence during life. That is, we may have obstruction by invagi-

[1] Read before the Framingham Medical Society, December 4, 1900.
[2] At the autopsy of a child made by the writer, assisted by Dr. Sylvester, of Natick, it was found that numerous invaginations of the small intestines had followed upon a kick bruising the kidney. That this injury was the exciting cause of the invaginations was inferred from the history.

nation or otherwise, without great tympanites, tenderness, obstinate vomiting, etc., and with the occasional discharge of fecal matter in the stools. Dr. Benjamin Phillips found in 169 cases of fatal obstruction from all causes 63 cases of invagination. It should be borne in mind that obstruction of the bowels may remain latent for a long time.

In a valuable monograph[3] a record is found of 56 cases. An erroneous diagnosis was made in 27. In some of these a wrong diagnosis was made several times and by different men. In 10 cases only was a correct diagnosis made. Obstruction of some sort was, however, made out in 18 cases, if we admit among these 3 of worms, 1 of abscess, 3 of prolapsus of the rectum, 1 of polypus of the rectum, and 6 of cancer or intestinal tumor. In 13 instances the diagnosis shows apparently no suspicion of any obstruction of the intestines. Among the various diagnoses were 1 of fever, 1 of some inflammatory process, 1 of cancer of the stomach, 1 of ulcer of the stomach, 1 of dyspepsia, 1 of peritonitis, 1 of peritonitis with gastro-enteric ulcer, 1 of gastro-enterocolitis, 1 of poison, 1 of flux of the bowels and 3 of chronic dysentery.

By carefully sifting the evidence upon which these mistaken diagnoses were based, Raffinesque finds that the first and most important differential diagnosis is between obstruction and *dysentery*, or some ulcerative or irritative process going on in the intestinal tract accompanied with occasional colic pain with bloody or slimy matter in the stools and tenesmus. This description would embrace more than half of the errors above enumerated.

(1) In dysentery, chronic or acute, there is fever, marked by high temperature, thirst, a hot skin, etc., symptoms that are rarely, if ever, observed in intussusception.

(2) In the latter there is tenderness at a particular spot in the belly, which serves as a guide to the seat of the trouble. This is not true of dysentery. Whenever this symptom is present in a case of presumed enterocolitis, enteric ulcer, flux of the bowels, or other dysenteric conditions, ether should be given and the abdomen thoroughly explored over the region of tenderness, the most important pathognomonic indication being the finding of a tumor at the point indicated by the tenderness; ether aiding materially in this exploration by relaxing the abdominal walls, which on pressure become tense and resisting by pain.

(3) The occurrence of colic pain in paroxysms; a symptom almost invariably present in invagination, and very unusual in dysentery. In chronic cases, especially in thin subjects, the intestines can be seen and felt writhing and rising up against the abdominal wall, and giving valuable evidence of the presence of obstruction.

(4) It is important to remember the frequency of invagination as a cause of intestinal obstruction in infants, and exploration of the rectum should be added to the other means of diagnosis. Of course in dysentery no tumor would be found, but impacted feces, foreign bodies, constrictions, ulcers and sometimes invagination, might be thus disclosed.

(5) The history of the case. In favor of obstruction of some sort there may be hernia, external or internal, reduced or unreduced; the fact that indigestible things have been swallowed, hair, for example, or calcined magnesia; a history of the existence of some tumor; of wounds or injuries; of peritonitis or typhlitis, with probable adhesions; or of invagination recovered from in childhood; and perhaps paralysis, lead poison, and possibly syphilis. On the other hand, in favor of dysentery or some intestinal ulceration there would be a history of fever, and as an explanation of tenesmus and hemorrhage there may be such things as cirrhosis of the liver, embolism of the superior mesenteric artery, and perhaps other disorders. A case is reported also of bowel obstruction caused by diphtheritic membrane.

In view of the great relative importance of invagination in fatal bowel obstruction, being about 40% of all the causes put together, the following diagnostic picture is valuable: Constipation, with repeated attacks of a dysenteric nature, but without marked fever; paroxysms of colic pain with tenderness in a particular point, and the presence of a sausage-shaped tumor not accounted for by anything in the previous history, are very strong points in establishing the diagnosis of intussusception. In infants this diagnosis is often very difficult, and cases are recorded of invagination in children with no other marked symptom than occasional bloody stools.

The second differential diagnosis, judging by these cases of Raffinesque, is that from chronic and tubercular peritonitis, especially in young subjects.

(1) Vomiting. This symptom is almost invariably present at some time or other in obstruction, while in chronic peritonitis it rarely occurs except from special cause.

(2) The colic. This is perhaps the most common and constant symptom of intestinal obstruction, and occurs in occasional paroxysms. In chronic peritonitis the pain, if any, is usually dull in character, not paroxysmal, and not accompanied by straining and tenesmus.

(3) Tenderness in one particular point. This is characteristic of obstruction, and is very seldom marked in chronic peritonitis, although in infants we may find it difficult to establish this fact.

(4) Emaciation. This is very marked in cases of chronic peritonitis; whereas, according to Rilliet, it is by no means extreme in invagination or in more or less partial obstruction in infants.

Moreover, examination under ether enables us usually to establish the fact of the non-existence of any foreign body or tumor pressing upon the intestine or obstructing its lumen from within. Ileus, volvulus, invagination are only three names for the same condition, although the etiology may be different. In appendicitis there is seldom any call for a differential diagnosis, as obstruction does not occur until a perityphlitic abscess has formed and is pressing upon the bowel.

Catarrhal enteritis, however, sometimes closely resembles invagination, and has been mistakenly diagnosticated. In both there is constipation, sometimes alternating with small thin stools, with localized colic pain and tenderness and a sausage-shaped tumor. The diagnosis here is based upon different grounds than those above mentioned. In invagination there is usually blood in the stools, retching and vomiting from the first, with complete absence of fever, while the tumor, which is upon the left side, can be felt writhing in the effort of straining. Hugo Engel, of Philadelphia, in a paper on "The Localization of Intestinal Catarrh," says, "If the dejections show the

[3] Etude sur les Invaginations intestinales chroniques par le Dr. F. G. Raffinesque, Paris, 1878.

typical bile-pigment reaction we may conclude that the bowels are pervious, and that peristaltic action is continuous throughout the whole tract."

Lead poisoning has been mistaken for intestinal obstruction. Here the diagnosis must be derived chiefly from the history. In syphilis the obstruction, according to Mr. Bryant, is caused by ulceration, especially of the rectum.

The most important differential diagnosis from the point of view of treatment lies between strangulation and impaction or closure of the intestines, occluding the lumen, whether from within or from without. When palpation under ether fails to disclose the nature of the tumor, the anamnesis is of importance. The family tendency, the fact of injury or of surgical operations, of previous attacks of similar nature, of hernias, reduced or not, of the ingestion of indigestible substances, poisons, etc., should be inquired into. The clinical history usually enables one to decide between the acute and the chronic, the febrile and non-febrile, complete and partial forms. Examination per rectum should never be omitted, and much may be accomplished in certain cases by the persistent use of high-up injections. The employment of purgatives or opium is both misleading and dangerous, and the only word to say about treatment is this, namely, that whenever the diagnosis of intestinal obstruction, acute or chronic, whether by invagination, occlusion or strangulation, is made, a surgeon should be called to the case. The operation of celiotomy in experienced hands is comparatively safe, and may be the means of saving many lives. The fatal result comes usually from overdistention of the gut above the seat of obstruction. None of the means pointed out should be neglected, so that one may arrive without delay at a correct diagnosis. No positive and definite line can be drawn, however, which will apply to all cases, and death has been known to occur from intestinal obstruction in forty-eight hours and even less, without severe pain, marked distention or much vomiting.

Clinical Department.

A PHYSIOLOGICAL SOLVENT IN THE TREATMENT OF PUS GASES.[1]

BY CARL E. MUNGER, M.D., WATERBURY, CONN.,

Assistant Surgeon, Manhattan Eye and Ear Hospital, New York; Laryngologist and Aural Surgeon, Waterbury Hospital, Waterbury, Conn.; President of the New Haven County Medical Association.

THE physiological function of gastric juice is to break down and dissolve all the alimentary proteids, converting them into soluble albumoses and peptones. The gastric juice is also antiseptic and bactericidal, and thus not only enables us to appropriate food, but confers in health a certain immunity against sources of infection in food and drink. These are no doubt familiar facts; but when my attention was recently called to the use of an artificial gastric juice as a solvent for pus and broken down tissue, they took on a new significance. The technical employment of artificial digestion *in vitro* in the production of peptones from various food proteids is already long established. The proteid matter of suppurating tissue is in its nature quite as responsive to the enzymic action, and is even more penetrable than ordinary masses of food.

I was, therefore, impelled to give consideration to this suggestion, new to me, of gastric juice as a physiological solvent, as presenting on *a priori* grounds obvious advantages over chemical agents. In H_2O_2, for instance, which is of undoubted value, there is the disadvantage of its creating much gas, which produces pressure, which pressure may be beyond our power to control. Whilst the broken down tissue is not destroyed, the soluble substances into which it is converted by enzymic action are readily removed by irrigation, and the artificial gastric juice itself is incapable of producing systemic poison.

The product which I have used, enzymol, is a sterile fluid, which, when diluted with an equal volume of water, has about the acidity of normal gastric juice, and is then suitable for use in most cases. It possesses great proteolytic energy. It exhibits marked action as an antiseptic and deodorizer, offensive odors yielding to a few applications. It has agreeable qualities, and does not produce irritation except in cases of sensitive mucous membrane.

In some cases the matter readily yields to the solvent; in others it is necessary to keep the solvent in prolonged contact, with repeated washing and renewed application. In every case the procedure is based upon the fact that the action is essentially physiological, not at all similar to that of a chemical which instantly attacks the surface it touches.

CASE I. The first case that I used this on was an old middle ear and mastoid case in which there had been a foul-smelling discharge from the external ear, and also behind the ear through a fistula in the mastoid bone. Three injections of a 50% solution of enzymol at intervals of twenty-four hours stopped the discharge entirely. There has been no further discharge, now seven weeks after its use — this without any other treatment. This ear had been continually running for two years in spite of frequent cleansings and treatments with H_2O_2, boracic acid in powder and solution, corrosive-sublimate solution, aristol, iodoform, iatrol, etc.

CASE II. Acute purulent otitis media. The patient, a girl twelve years of age, came to my office January 11th with a typical case of otitis media acuta purulenta. The ear had been running ten days. The discharge was copious but not foul smelling. This was treated with injections of hot boracic-acid solution, followed by instillations of H_2O_2, into the ear three times a day for twelve days. I then injected a 50% solution of enzymol into the ear, and instructed the mother to do this twice a day. Eight days later the patient returned with the history that after the injections had been used three times at home the discharge had entirely ceased, and there had been no more discharge. Examination showed that there was no discharge, and that the hearing was practically normal.

CASE III. Young man, age twenty. Polyps in both ears, or rather stumps of snared-off polyps. There had been a very offensive discharge for months, which had been aggravated by an attack of influenza. One week's use of enzymol, an injection of 5 drops of a 50% solution twice a day, stopped the discharge in a week, and the accompanying foul odor. Seen a week later there was still no discharge and no odor.

CASE IV. Baby, one year old. Vaccination sore,

[1] Read before the Waterbury Medical Society, November 12, 1900.

deeply ulcerated and covered with foul-smelling pus and broken down tissue. Four applications, at intervals of twelve hours, of a 50% solution of enzymol caused the ulcer to be dried, healed and non-odorous. At the first application there was considerable smarting, lasting a few minutes. The subsequent application caused no pain.

CASE V. Adult, female. Ulceration of triangular cartilage of months' standing. One application thoroughly rubbed in caused this to heal, though it again ulcerated some weeks after.

CASE VI. Baby, cervical abscess. Abscess opened, washed out with enzymol once, entirely healed three days later.

CASE VII. Girl, eight years old. Abscess of neck due to broken down lymphatic glands. Opened and enzymol used daily. This was a case which should properly have been curetted, but I wished to see if enzymol would disintegrate the remainder of the gland which was not broken down. It did not do this, but did keep the wound sweet and clean, with a healthy granulating surface.

CASE VIII. Abscess of arm in a man, probably tubercular. This was opened, and enzymol, 50% solution, injected into the abscess cavity, which was healed in two days.

CASE IX. Ulceration of septum, syphilitic, with troublesome formation of crusts. Enzymol used, 33% solution twice a day for one week, almost entirely relieved the patient of this condition.

CASE X. Boy, fourteen years old, came into the Waterbury Hospital with an abscess probably appendicital in origin. This was opened and 16 ounces of foul-smelling pus with broken down tissue was evacuated. Enzymol, 50% solution, was used in this cavity, with the effect of quickly stopping the foul smell and the formation of pus. The enzymol was injected twice daily and later every other day. The cavity is healed, there being only a small sinus left, which is quickly healing. The enzymol was left in the cavity ten minutes and then washed out with normal salt solution. The wound became infected shortly after the operation, and was covered with a thick fibrinous deposit. The effect of enzymol on this was particularly interesting and instructive. It could be seen to dissolve the membrane and leave a bleeding, healing surface.

CASE XI. Man, a caster, injured by having molten lead fall in top of shoe between shoe and foot and burning the top of foot severely. This wound was seen three days after injury, and the condition was as follows: A destruction through entire thickness of skin forming an ulcer 2 inches in diameter and covered with a foul-smelling slough. This wound was treated by binding absorbent lint soaked in 50% solution of enzymol, and at the end of three days the appearance was that of a clean, healing, granulating wound.

CASE XII. Man. Extensive cellulitis of front and side of chest wall. In this case large amounts of enzymol were used by injection through drainage tubes, and into several deep pockets formed by broken-down cellular tissue. The results here were extremely satisfactory, as the enzymol fairly dissolved the broken down tissue so that it could be easily washed out through the drainage tubes.

I tried enzymol in a case of chronic cystitis, but was disappointed in its action, as from its former use I was led to believe that I had found a remedy *par excellence* for this troublesome class of cases. I used both a 50% and 33⅓% solution, but the symptoms were aggravated, and I abandoned its use for other remedies. In another case I should recommend a much weaker solution and should hope for better results.

I have used this remedy in nasal wounds, such as division of synechiæ and operations on the septum, with the results of finding that the wounds kept sweet and clean and healed readily.

This can hardly be called more than a preliminary report, but the results have been so satisfactory thus far that I feel justified in reporting them, and shall continue this method of treatment in these classes of cases in which at this writing it seems to me of value and scope yet to be fully determined. This remedy appeals to me as being especially applicable for use in diseased cavities, sinuses and fistulas, and wherever there is found broken down tissue — bony, lymphoid, muscular or cellular.

I believe that solutions of enzymol may be used much weaker than the 50% solution which is recommended, and in fact must be so used on mucous membrane to avoid undue irritation.

When using enzymol in mastoid cases and suppurating middle-ear cases, I find that these cases do better when the enzymol is used thoroughly and *injected* into the middle ear or through the mastoid wound, not merely dropped in.

Reports of Societies.

THE NEW YORK OBSTETRICAL SOCIETY.

STATED meeting, November 13, 1900, the president, DR. H. J. BOLDT, presiding.

DR. E. B. CRAGIN presented a patient upon whom operation had been performed for

FULL-TERM ECTOPIC GESTATION,

the child being alive, in perfect condition, and presented with the mother to the society. Mrs. K. W., age thirty-three years, a German, was admitted to the Sloane Maternity Hospital, October 16, 1900, with the following history: She had been married eight years, had two miscarriages, one at six, the other at four months, menstruation had been regular, and there was no history of endometritis or pelvic trouble of any kind. She had her last regular menstruation in January, 1900. In February she flowed for two weeks. In March she had a severe attack of abdominal pain which kept her in bed one week. After this she was well, except for alternating constipation and diarrhea during pregnancy. "Life" was felt in June. She had had pains in the back for two weeks before admission, and for two days before admission she had had several pains in the abdomen. On admission the pulse was 120; abdominal examination was negative on account of tympanites and rigidity of the abdominal walls.

Vaginal examination showed the vertex low down in the posterior cul-de-sac, almost on the perineum. High up behind the symphysis the finger could just reach the posterior lip of the cervix, but could not enter the cervical canal. As delivery *per vaginam* seemed impossible, it was determined to enter the abdomen. It was then found that the case was one

of full-term ectopic gestatation, within the folds of the left broad ligament, pushing the uterus up against the anterior abdominal wall and dissecting the peritoneum from the posterior wall of the uterus. As a result of forty-eight hours of spurious labor, the ectopic sac was found ruptured and the intestines covered with fresh fibrin stained with meconium. The point of rupture was quickly dilated with the finger and the living child extracted, which is here presented. The placenta was chiefly attached to the left broad ligament, and it was found that the maternal vessels supplying the area could be ligated. The uterus was so incorporated with the sac that it was decided to remove it, the sac and placenta *en masse*.

The patient has had a smooth convalescence. The baby was kept in an incubator for one week, then for one week in cotton, and since then it has been out of cotton. At birth it weighed 5 pounds, and now weighs 5 pounds and 7 ounces.

Dr. Cragin again drew attention to the fact that the viable ectopic fetus was worth saving, and with certain limitations, attempts to save the child do not seriously increase the mortality to the mother, and that the child in ectopic gestation should receive more consideration than it enjoys. He believed that at present, in the majority of cases, the placenta is so attached that it is safer not to remove it as the primary operation, but that occasionally, as here, the attachment will be such that the maternal blood supply can be ligated and the placenta safely removed.

DR. E. A. TUCKER emphasized the importance of making an early diagnosis of spurious labor, for the reason that operation could then be successfully performed, whereas in the later cases the mortality to the child in particular was necessarily great.

DR. CRAGIN said that the best time to operate was two weeks before full term, so as to get ahead of the spurious labor, and in this way get a living child.

DR. A. BROTHERS presented a specimen of

MALIGNANT CHORION EPITHELIOMA, OR SO-CALLED DECIDUOMA MALIGNUM.

The patient was twenty-four years of age; menstruation regular up to June, 1899, when, after bleeding for a month, she had an eight weeks' miscarriage. In June, 1900, after suffering considerable pain due to delayed menstruation, she began to bleed, and lost so much blood that on June 21st she was curetted. The scrapings were examined and showed no evidence of malignancy. She remained well for two and one-half weeks, when bleeding came on in an irregular manner, would last several days and then disappear for two or three days.

Suspecting the condition known as deciduoma malignum, the patient was anesthetized, and the long conical cervix dilated, after which it was incised laterally to a depth of 1 inch. The cavity contained a small tumor, found later to consist of myxomatous tissue, with no evidence of malignancy, and the interior of the uterus was subjected to a thorough curettage. After irrigation, the incisions were closed, everything pointing against malignancy. The patient remained well until the last week in September, when she had another exhaustingly profuse hemorrhage with large clots. This was succeeded by such a large hemorrhage that a doctor called to the house was obliged to pack the vagina with gauze and transfer her to the hospital. The vagina was douched several times, and then repacked without benefit. The cavity of the uterus was then swabbed daily with 95% carbolic acid, and then for a few days with 10% ferriphyrine. On October 25th the house surgeon of the hospital did a curettage, but in spite of the presence of some foul-smelling tissues still left in the uterine interior, he was obliged, on account of fearful hemorrhage in the almost pulseless patient, to suspend the operation and rapidly pack the uterus and vagina to their full capacity with iodoform gauze. There was now no doubt that radical operation alone could be of any avail, and preparation was made for vaginal hysterectomy. The operation was performed under intraspinal anesthesia, and while one of the staff injected several quarts of saline solution into one of the veins of the elbow, the uterus was quickly removed, about seven minutes being required. The patient made an uninterrupted recovery, although convalescence was slow on account of the anemic condition. The pathologist reported that he was inclined to designate the pathological condition as so-called "deciduoma malignum."

DR. J. E. JANVRIN presented a specimen of a

LARGE MULTILOCULAR FIBROMA OF THE UTERUS,

removed by abdominal hysterectomy. The patient was forty-five years of age, and had had a miscarriage at about the fifth month, twelve years ago. Two and one-half years ago, she noticed an enlargement in the right pelvic region, and since that time a gradual increase in size has taken place. In certain months the menses have been more profuse than usual, but general health has been good. In July of the present year examination revealed the presence of the fibroma, its apex extending upward to the right of the median line, for a distance of four fingers above the line of the umbilicus, crowding up against the liver and under the false ribs. There were numerous adhesions in the pelvic cavity, and no mobility of the mass in its lower half, but the upper half was movable. Tonics were given, and frequent hot douches ordered, in order to prepare the patient for operation. In October, with the patient in good condition, hysterectomy was performed, the operation requiring two and one-half hours on account of the difficulty in breaking up adhesions. The bladder had become firmly adherent to both the anterior surface of the tumor and the abdominal wall, its fundus reaching almost to the umbilicus. In spite of the utmost care in making the incision, the bladder was entered, the escape of urine into the abdominal cavity being prevented by the strong adhesions formed. The opening through the bladder wall was immediately closed, and the incision continued upwaard nearly to the sternum, which enabled the operator to dissect the bladder from the tumor. The broad ligaments were finally clamped and ligated and hemorrhage effectually controlled. The whole mass was then lifted from its capsule of adhesions, and removed, leaving about ½ inch of cervix to form a roof for the vagina. Peritoneal tissue from the posterior wall of the tumor, with capsular tissure, made a thorough covering for the stump, ligatures and cervix, thus leaving the abdominal cavity free from raw surface. The shock of the operation was considerable, and several quarts of warm normal saline solution were left in the abdominal cavity. The patient made a satisfactory recovery. The weight of the tumor was 8 pounds.

Dr. Janvrin then presented a specimen of

CANCER OF THE UTERUS,

abdominal hysterectomy being complicated by an ovarian tumor. The patient was fifty-nine years of age; she had had one child thirty-four years before, and was badly lacerated at its birth. Five years ago the cervix and perineum had been repaired, and there was no evidence of malignant disease. Sudden hemorrhages occurred in July and September, and the cervix was curretted by a physician in another city, who advised against radical operation. In October Dr. Janvrin found the cervix to be the seat of a cancerous infiltration, and there was also a tumor occupying, as it seemed, the body of the uterus. The mass was so hard and firm, of the size of an infant's head, that diagnosis of fibroma was made. Radical operation was performed in November. The tumor was found to be a very tense and inelastic ovarian growth, originating in the left ovary, and firmly bound down to the fundus by old adhesions. The contents were evacuated, and the sac removed with the uterus, the cavity being well filled with iodoform gauze, reaching down and out of the vagina. The pathologist reported the case to be one of rapidly developing epitheliomatous infiltration. Dr. Janvrin stated that it was not his usual custom to remove the uterus where the disease had extended into the parametrium, but in this case there was doubt and there had been the ovarian tumor to be removed also. The patient has made a good recovery from the operation, but further extension of the disease was to be expected.

DR. BROTHERS remarked that the case was interesting because of the fact that the operation was preceded, five years before, by a trachelorrhaphy He believed that the impression existed that trachelorrhaphy had an influence in preventing cancer.

DR. JANVRIN stated that this was the first case in his experience where cancer of the cervix had developed after trachelorrhaphy had been done. At the time of the operation five years before, the sections of cervix which were removed were thoroughly examined, and there was no evidence of malignancy.

The paper of the evening was read by DR. SIMON MARX. His subject was

MY FAILURES AND SUCCESSES WITH SPINAL ANESTHESIA.

The peculiar title of the paper about to be read will at once attract the attention I wish, for I am fully prepared to report the failures of this procedure. I have already so covered the ground of my successes that many would imagine that spinal anesthesia cannot fail. No method, mechanical, therapeutical or surgical, has ever been used without its quota of failures. My successful punctures were so continuous that I never expected a failure. It was only after doing from 60 to 70 punctures that my failures, 2 in rapid succession and for one operator and before one audience, occurred, placing me in as humiliating a position as any honest investigator could possibly be. They were such convincing failures that only the veriest dreamer could have thought them otherwise.

As to my successes I have little to say, since I have said enough in other places. So far as I am concerned, "Be the destiny of the method what it may, to you," I know from a very large experience what I can do with medullary narcosis. I do not need to defend this little operation; it needs no defence. We realize its possible dangers, immediate and remote; we know it occasionally fails, and we do not expect too much from it, for spinal anesthesia will never take the place of cerebral anesthesia, for its sphere will ever be limited to well-defined cases.

I know it will please you not alone that Corning originated this operation, but that the first extensive original experiments were done by two Americans, Drs. Dudley Tait and Guido Caglieri, of San Francisco, Cal., and published by them in the *Transactions of the Medical Society of the State of California*, April, 1900, under the heading, "Experimental and Clinical Notes on the Subarachnoid Space." The experiments, both physiological and clinical, are the first extensive experiments on record pertaining to cocainization of the subarachnoid space.

I have had in the neighborhood of 100 punctures with 2 failures. Both occurred in intensely neurotic women (Italians) upon whom pelvic operations were to be performed. By careful analysis as to the causes of these failures I am able to exclude all but an idiosyncrasy to the drug and again to the highly nervous condition of the patients. The more nervous a patient the more likely is the spinal anesthesia to fail. The possible causes of failure may be enumerated as follows:

(1) *Inert cocaine solution.* — Repeated sterilization absolutely spoils the cocaine. We never employ a solution that has been boiled more than once, but have the solution freshly prepared for each patient; at least it should not be more than one day old.

(2) *Too little of the drug used.* — This is a factor that can never be gauged, since a small dose will bring success in one case, and absolutely fail in another. In obstetrics we find from a study of our cases that between $\frac{1}{4}$ to $\frac{1}{3}$ of a grain is sufficient. In surgery we certainly have seen most brilliant results from smaller rather than larger amounts, from $\frac{1}{8}$ to $\frac{1}{4}$ grain. We have never been compelled to give a larger individual dose, and we would consider doses of from $\frac{3}{4}$ to 1 grain highly dangerous.

(3) With an imperfect syringe backing of the solution behind the sucker would cause the fluid to be ejected instead of injected. For this reason after the injection we always slightly withdraw the piston to be sure that this does not take place. Of course here comes the advantage in using a glass instead of a solid metal hypodermic.

(4) Idiosyncrasy is a condition that can never be foretold. It is a well-known fact that cocaine will never bring certain patients under its influence, no matter where or by what means used. This condition is especially associated with highly nervous and hysterical patients.

(5) *Faulty technique.* — Where care is used in following carefully the directions given, success in the largest majority of cases follows. The largest numbers of failures are due, we believe, to non-entrance into the canal, whether due (*a*) to faulty technique, or (*b*) to too short needle; the average needle should be about 10 centimetres long, but the distance to be traversed will rarely exceed 6 to 7 centimetres. Of course in a very obese patient it may be necessary to exceed this distance, but this seldom is the case. (*c*) A very dull needle point may, by pushing the membranes before it, prevent entrance of the fluid, and yet, on the

other hand, a very large pointed and sharp needle may throw the solution beyond the canal. For this reason my points are exceedingly short, more on the trocar order, for long points may wander beyond parts under control and prevent what is essential to success, the escape of spinal fluid. (*d*) Again, very large-calibre needles, by making inordinately large apertures in dura and pia spinalis, predispose to the extravasation of our medicinal fluid. Therefore it is wise after the injection to hold the needle in place for a minute or so in all cases, but it is best overcome by using exceedingly fine aspirating needles for this purpose. (*e*) Disturbing the relation of the needle point to the canal while screwing or fixing on the barrel is a not uncommon possible cause; for, if clumsily done, it is possible to withdraw a short bevel, and by such faulty action throw the cocaine outside of the canal.

The author then described the correct technique of the operation: The injection is given between the fourth and fifth space, but the space between the third and fourth lumbar is equally desirable. Tait, in his experiments, and in his operative work in 3 cases, speaks highly of the sixth cervical space, as a way that is sure and extremely easy in the human being. We, nevertheless, object to inject in this area for the sole reason that the solid cord lies here; further, that the nearer the skull cavity the cocaine is injected the greater the toxic influence of the drug. We have been so well satisfied with the fourth lumbar space that we always elect it when at all possible. To ensure absence of pain from the puncture through the skin, a freezing spray is used. From 8 to 15 metres (as the needle holds about 3 metres we must allow for this, and the barrel of the syringe charged with the exact amount) of a 2% solution is used, representing between $\frac{1}{6}$ to $\frac{1}{4}$ grain of the salt. The needle is held *in situ* for a minute to plug the arachnoid puncture and ensure the impossibility of its escape, then withdrawn and the puncture sealed. Within from two to three minutes anesthesia is ushered in, occurring somewhat suddenly, occasionally preceded by a marked hyperesthesia. There is often trembling of the limbs, and a feeling of formication in the affected areas. Vomiting often accompanies the symptoms, but is very evanescent. Operation can usually be commenced as soon as firm pinching or pulling upon the labia elicits no pain. If at the end of fifteen minutes the desired result is not obtained, the injection of a smaller dose may be repeated. My clinical experience has taught me that the area of anesthesia varies considerably, and cannot be influenced by either the dose given or the force with which the solution is thrown in.

The post operative symptoms are due to a disturbance, in part, of the equilibrium in the subarachnoid space, and could be avoided by the preliminary extraction of a small amount of fluid, and by making the injection slowly. Again, the amount of cocaine was an important factor. With more than $1\frac{1}{2}$ cubic centimetres of a 1% solution, or more than 1 cubic centimetre of a $1\frac{1}{2}$% solution, we generally noted nausea, headache and weakness. Nirvanin and eucaine produce less analgesia and disappear more rapidly.

Tait and Caglieri conclude (in part) as follows:

(1) To the lumbar route they propose to add the "low cervical" in the sixth cervical space — both easy and safe.

(2) Direct intramedullary medication is feasible and deserving of further trial.

(3) Subarachnoid injections are devoid of danger if made with certain precautions. The solution should be freshly prepared and injected slowly at a temperature of 37° C. and never in greater amount than 3 cubic centimetres.

(4) The extent and duration of the analgesia thus induced are generally in direct proportion to the amount of the drug injected. Analgesia is noted in some cases as early as five minutes after the injection, and in others, for unknown reasons, as late as thirty-five minutes. Its duration is sufficient for the performance of all operations on the lower limbs and pelvis, and may be of service in obstetrics.

(5) The disagreeable effects sometimes noted are partly due to the sudden increase of pressure in the subarachnoid space, to too rapid diffusion towards the brain, and principally to the amount of cocaine used. These post-operative symptoms are never alarming nor lasting. They recall the intradermic effects of cocaine, and never resemble in severity the symptoms so frequently observed during or after chloroform or ether anesthesia.

(6) One cubic centimetre of a 1% solution of cocaine, injected slowly, is generally sufficient for all practical purposes, and has not been followed by untoward results.

(7) For obvious reasons it is a good plan to withdraw a small amount of cerebrospinal fluid prior to making an injection.

A last and very potent factor combining to make an otherwise good narcosis a failure is noise, bustle and excitement during the operation. These patients must be protected from extra annoyances, at least excusable or avoidable ones, whether by obtunding their otherwise markedly increased powers of sight and hearing by medical means, as a preliminary dose of morphine, or mechanical, which I consider far better, that is, plugging the ears and blindfolding them, or by means of a screen, shutting off their power of sight. As to measures directed against the post-operative symptoms, we still pin our faith to the bromides given in large doses, 30 to 40 grammes, one to two hours before the operation. This drug has answered us admirably in many cases. Possibly a combination with caffeine might enhance the value of its effect. Personally we have no experience with this combination, but caffeine has been highly lauded by others; a combination of both might be exhibited with more beneficial effect. Where no result is obtained from the bromides, and the vomiting persists, which is unusual, or the headache and the other symptoms are pronounced, hyocine hydrobromate in doses of $\frac{1}{200}$ to $\frac{1}{100}$ grammes as a powerful cerebral sedative is of considerable value. We still retain the use of nitroglycerin where cyanosis or dyspnea becomes apparent. But since we have never seen this condition in labor, we have had no occasion to use it.

Now as to my labors, over 40 in number: Motor disturbances of the uterus we have never seen, for the uterine contractions go on regularly, and under their influence the os dilates as under normal conditions; and all this time while the patient has some indescribable sensation, but not one of pain, she is delivering herself as naturally as if her symptom of pain was not masked. Under these conditions we only recognize the powerful contractions either by placing the hand on the abdomen, or by exposing the protruding

and bulging bag of water or the advancing head. Reflex action of the abdominal muscles was found present only when incomplete anesthesia existed, and was then accounted for by the presence of pain. But when anesthesia was complete, spontaneous bearing down did not occur; voluntarily the muscles were not called into play; only when told to do so was the patient capable of bringing her abdominal muscles into play, and then as powerfully as under normal conditions. This I have always encouraged to further the *vis a tergo* in normal labors. I have done some extremely difficult operations under spinal anesthesia; in fact, all forms of obstetric operations were undertaken, except symphyseotomy and Cesarean section. Explorations, versions, forceps extraction, placental removal were done, not with as great ease as under chloroform, but with much greater facility than in a non-narcotized (chloroform) woman. It was never necessary to finish any operation under a general anesthetic when commenced with medullary narcosis. Relaxation of the uterus or even spasm of a severe grade was never encountered, nor was there a greater disposition to bleed than under ordinary conditions. We have never met involuntary evacuation of bowel or bladder such as occasionally occurs in surgical practice, even as often happens when ether or chloroform is administered, or as occasionally happens during labor under normal conditions. In all cases where cocaine was employed we obtained the happiest results. In no case were any bad symptoms noted, except in 1 case, where, by mistake, with the cocaine $\frac{1}{4}$ grain of morphine was administered. The patient developed all the symptoms of a grave opium poisoning, and required pretty heroic measures to bring her out of her soporous condition.

Dr. A. Palmer Dudley commented favorably upon the happy results Dr. Marx had obtained in obstetrics, but said that in general surgery he had used the method in 1 patient for amputation of the leg below the knee, with the result that within a few hours convulsions came on, twelve in number, the temperature rose to 103°, the pulse to 120. The urine was loaded with sugar, uremic conditions supervened, and the patient died. In another case he obtained intense reflex action, for which he used bromides. There were no convulsions and the patient did nicely. The third case he had had was one in which he did a curettage and divulsion for vaginismus. Twelve hours after the operation she became a raving maniac. Her temperature was 103°, and pulse 120, and the headache intense for nearly two days in spite of bromides. The patient, however, recovered nicely. All 3 cases had involuntary stools and incontinence.

Dr. Austin Flint, Jr., reported excellent results in 1 case of labor, but unsatisfactory results in 2 others. The headache was the worst feature.

Dr. Marx stated that he had never seen involuntary stools or urination in his cases, and a friend who had used the method for 37 operations had had no bad effects in that way.

Typhoid Fever at Galveston, Texas. — Typhoid fever prevails widely in Galveston, according to the *Medical Record*, the estimated number of cases in the city being about 500. It is believed that the infection is spread by the use of cistern water, contaminated at the time of the great storm.

Recent Literature.

Heart Disease in Childhood and Youth. By Charles W. Chapman, M.D. (Durh.), M.R.C.P. (Lond.), Physician to the National Hospital for Diseases of the Heart, Soho Square, E.; late Physician to the Farringdon Dispensary, E. C. With an introduction by Sir Samuel Wilks, Bart., M.D., F.R.S., Physician Extraordinary to H. M. the Queen; ex-President of the Royal College of Physicians, and Consulting Physician to Guy's Hospital. London: The Medical Publishing Company, Ltd. 1900.

Dr. Chapman has prepared a very readable little book. While it is scarcely to be expected that one should find a great deal that is new on a subject which has lately received much attention, the author is to be commended for the common-sense way in which he has handled it. The first portion of the book gives a brief outline of the "more usual varieties of heart disease as they occur in young persons," to quote from the preface, while the latter part is made up of illustrative cases which serve as a text for remarks on treatment and prognosis. The latter are always to the point and give valuable suggestions as to the management of these cases.

The Practice of Medicine. A Textbook for Practitioners and Students, with Special Reference to Diagnosis and Treatment. By James Tyson, M.D., Professor of Medicine in the University of Pennsylvania, and Physician to the Hospital of the University, etc. Second edition. Thoroughly revised and in parts rewritten, with 127 illustrations, including colored plates. Philadelphia: P. Blakiston's Son & Co. 1900.

It is four years since the appearance of the first edition of Dr. Tyson's "Practice of Medicine." This second edition, an octavo volume of 1,222 pages, deserves the same favorable comments as were made upon the first edition, with the additional statement that it has been revised and enlarged where needed in accordance with the progress and changes which have taken place during the intervening period. Of the changes the most numerous are to be found in the sections on the Infectious Diseases and on Diseases of the Nervous System.

The index also has been revised and enlarged as required by changes in the body of the book.

A Manual of Modern Surgery. An Exposition of the Accepted Doctrines and Approved Operative Procedures of the Present Time. For the Use of Students and Practitioners. By John B. Roberts, A.M., M.D., Professor of Anatomy and Surgery in the Philadelphia Polyclinic; Mutter Lecturer on Surgical Pathology of the College of Physicians of Philadelphia. Second edition, revised and enlarged. Illustrated with 473 engravings and 8 plates in colors and monochrome. Philadelphia and New York: Lea Brothers & Co. 1900.

The author believes "that a volume from a single pen may be more equable in its teachings than a composite book from many minds," and this second edition of his book demonstrates its success. The book is certainly one of the best, if not the best, single volume textbooks on surgery.

The articles on Appendicitis, Diseases and Injuries

of the Joints, Diseases and Injuries of the Genito-Urinary Organs, Dislocations, Excisions and Amputations have been entirely rewritten.

It is essentially a practical book, the descriptions being simple and concise. From the size of the book the treatment is of necessity dogmatic, but this, from the student's standpoint, is perhaps a virtue rather than a fault.

The illustrations are, as a rule, satisfactory and are sufficiently numerous. They are evidently selected as typical of conditions, and not for the purpose of making "a picture book." It is a safe, conservative textbook to place in the hands of students and is thoroughly abreast with modern surgery.

Bacteriology and Surgical Technique for Nurses. By EMILY M. A. STONEY, Superintendent of the Training School for Nurses, St. Anthony's Hospital, Rock Island, Ill., etc. Illustrated. Philadelphia: W. B. Saunders & Co. 1900.

This is a volume of 190 pages, much more limited in scope than the usual textbook, the chief function of which is the instruction of nurses. As indicated in the title, the book confines itself to bacteriology, surgical technique and closely allied topics. Naturally the bacteriology is not of a profound sort, nor can the discussion of immunity and phagocytosis, for example, be regarded as of great value. The following sentence (page 31) is perhaps calculated to mislead: "The theory is now known as the Metschnikoff theory of phagocytosis, and assumes an educated white corpuscle and cell body." We confess to a doubt of the advisability of such information for nurses, particularly in view of the possibilities of the future. Where is it all to end, is coming to be a more and more pertinent inquiry. The details of surgical technique, with the many admirable suggestions of a practical sort contained therein, are timely and valuable. The book, as a whole, is written in a judicial spirit and will, no doubt, be of value. We only hope that future editions may not go further into the obscurities of bacteriological research. The binding, paper and illustrations of the book are all satisfactory.

Fractures. By CARL BECK, M.D., Visiting Surgeon to St. Mark's Hospital and New York Polyclinic, etc. With an appendix on the Practical Use of the Röntgen Rays. Pp. 235, with 178 illustrations. Philadelphia: W. B. Saunders & Co. 1900.

This book is intended to encompass in a systematic treatise the important essentials compiled from publications on the use of the skiagraph in fractures, also from data derived from the author's personal study and experience. A study of fractures in the living subject is rendered possible, and developed by the use of the Röntgen method.

The introductory pages describe the discovery and development of the x-ray by Röntgen, and enumerate the various ways in which it is an aid to surgery, especially in the diagnosis and treatment of fractures.

Part I deals with the subject of fractures in general, their classification, statistics, diagnosis, process of repair, the conditions which interfere with repair, treatment, etc.

Part II discusses the fractures of special regions classified anatomically.

The last 52 pages are devoted to the practical use of skiagraphy. Here is described the apparatus, the character of the electric current required, the fluoroscope, photographic plates, etc., also what tissues and objects are visible by this method, and what has been demonstrated in the different pathological processes, or different tissues of the human body. The writer briefly enumerates the different methods by which the process is made available to different conditions, and states its present limitations and possibilities; for example, one reads how to photograph gall stones or renal calculi, how to determine the size and shape of the stomach, the position, size or shape of the heart, the presence of pulmonary or subphrenic abscess, trichinosis and many other things.

In conclusion the possible sources of error in the use of skiagraphy are enumerated.

The book appears to be carefully written, and is a very good résumé of the subject to date. It is especially interesting as showing the influence and value of the discovery of Röntgen on medical diagnosis and treatment. It suggests many possibilities to the student of surgical pathology.

The illustrations are a distinct feature of the work. Many are skiagrams which are exact reproductions of photographic prints. They show exceedingly well the points emphasized by the author.

The work of the publisher is admirable in every respect.

A Manual of Diagnosis and Treatment of the Diseases of the Eye. By EDWARD JACKSON, A.M., M.D., Emeritus Professor of Diseases of the Eye in the Philadelphia Polyclinic, etc. Pp. 604, with 178 illustrations and 2 colored plates. Philadelphia: W. B. Saunders & Co. 1900.

This book, as the author says in his preface, is designed to aid in the actual work of dealing with disease, and therefore gives the place of first importance to the recognition and management of the conditions likely to be presented early in practice rather than the rarer diseases and more difficult operations that may come later.

Anything that Dr. Jackson writes is well worth reading, and this book is no exception to the rule. The arrangement of the book is excellent, and the style clear and concise. The opinions given as to etiology, prognosis and treatment are always conservative and safe. The book has not been utilized to advance any hobby of the writer.

There is a very useful chapter devoted to ocular symptoms and lesions connected with general diseases, in which each symptom or condition as it is mentioned is referred back to the page in the volume where it is described, that cannot fail to make the book of great value to the general practitioner as a book of ready reference.

The work deserves success and will undoubtedly be widely read.

Hernia. Its Etiology, Symptoms and Treatment. By W. MCADAM ECCLES, M.S. (Lond.), F.R.C.S. (Eng.); Assistant Surgeon to the West London Hospital, etc. Pp. 231. New York: William Wood & Co. 1900.

This book is not intended to be a complete treatise of the subject, but to contribute for the benefit of the medical profession some facts relating to the origin, symptoms and treatment of hernia which have seemed of practical importance and value to the author.

Hernia in its various forms is discussed: Inguinal

hernia, femoral hernia, umbilical, ventral, obturator, and lumbar hernia, also inflamed, irreducible, obstructed, strangulated, sciatic, perineal, ischiorectal, vaginal and diaphragmatic, hernia of the urinary bladder, ovary and vermiform appendix. Finally, the relation of hernia to life and accident assurance, public service, foreign service, etc., is considered.

The book is interestingly written and well arranged. One can, as one reads, distinguish what points have especially attracted the attention of the author, or have aroused his interest, such, as would naturally be the case, being more exhaustively presented.

The text is illustrated by 97 cuts and photographs, the latter especially showing excellently well clinical cases and the application of trusses. The volume is one which contains much relating to the subject which is interesting and well worth reading.

A Handbook of the Diseases of the Eye and their Treatment. By HENRY R. SWANZY, A.M., M.B., F.R.C.S.I. Seventh edition. Pp. 607, and 165 illustrations. Philadelphia: P. Blakiston's Son & Co. 1900.

The seventh edition of this popular book retains the alterations and improvements of the preceding editions, and has had added to it an account of Dr. Mackenzie Davidson's method of employing the Röntgen rays for the detection and localization of foreign bodies within the eyeball; an operation for ptosis by Mr. Mules; and three tables by Dr. L. Warner, giving action and values of the mydriatics, myotics and local anesthetics used in ophthalmology. Other minor changes have been made, all of which seem to have been well considered.

Diseases of the Throat, Nose and Ears. A Clinical Manual for Students and Practitioners. By P. MCBRIDE, M.D., F.R.C.P., etc. (Edin.), Fellow of the Royal Society of Edinburgh. Third edition, revised and partly rewritten. Edinburgh and London: Young J. Pentland; Philadelphia: P. Blakiston's Son & Co. 1900.

McBride's manual has been well known since its first appearance in 1892 as a reliable, conservative and satisfactory textbook. This is the second American edition, and does not differ materially from the first. The text has been added to in places, a little has been rewritten, and there are a few more cuts. This volume contains 744 pages, about a hundred more than the previous one, but this increase is in good part due to larger type. Most of the changes are simple insertions of paragraphs in the text, describing recent work, or the author's experience in the subject. A few unimportant new subjects have been added, such as the pharynx in myxedema, autoscopy, scleroma, myoma of the larynx, falsetto voice, inflammation of the lingual tonsil. Most American readers, at least, will be surprised to find that the subject of deviations of the septum still occupies the insignificant place that it did in the first edition. A short sketch of the Asch operation is added, but nothing about any other; while the author's accumulated experience has not justified him in taking out from this edition the following discouraging sentence: "My own experience has been that deviations of the septum are not a very satisfactory class of cases to treat, and unless the nasal obstruction is very marked, the patient if he be flippantly inclined, is prone to conclude that 'the game is not worth the candle.'" The subjects of tonsillitis and peritonsillitis are incomplete and confused with one another; there is but little improvement in this edition. The supratonsillar fossa is mentioned a few times, but neither the anatomy nor the pathology of these regions receives the attention which their importance requires. The tone of discouragement in giving the treatment for atrophic rhinitis has been changed to one of hope by the introduction of cupric electrolysis. The chapter on the accessory cavities has been enlarged, in accordance with the added experience of the author and recent literature. It is judicial and satisfactory.

The book is worthy of the popularity which it has attained, and in spite of a large number of recent rivals in the field will undoubtedly retain its share.

Modern Surgery, General and Operative. By JOHN CHALMERS DA COSTA, M.D., Professor of the Principles of Surgery and Clinical Surgery, Jefferson College, Philadelphia; Surgeon to the Philadelphia Hospital, etc. Third edition, revised and enlarged. Illustrated. Philadelphia and London: W. B. Saunders & Co. 1900.

As it is only two years since the publication of the second edition of this work, the fact that now a third appears can be taken as an indication of the popularity of this book, or the determination of its author to keep it fully up to date, or both.

The present edition in general attractiveness of appearance, arrangement of text, and excellence of press work resembles closely the handsome volume of 1898. Comparison of it with its predecessor causes one to note an increase in size. Its pages have increased in number from 883 to 1,083 and its illustrations from 386 to 493. This increase in the text is due partly to the introduction of new material and partly to the rearrangement of old, the table of contents showing slight changes, except in its increased number of pages.

It is written in the same direct style as formerly, and evidently the author had in view his former effort to eliminate all data or hypotheses liable to create uncertainty in the mind of the reader as to their correctness or efficacy. In short, everything obsolete, unsuccessful, uncertain or unessential was to be conspicuous only by its absence.

This plan is an excellent one for a student's textbook, provided the student is made to understand at the same time that he has not exhausted the subject of surgery by becoming familiar with its pages. The writer in his second edition carried this idea almost to its limit, and we cannot avoid the impression, as we examine the pages of his last work, that in this he has crossed the line, that at times the increase in subject matter has been made by the sacrifice of that directness, simplicity and positiveness which has been so attractive to the student, and so prominent a characteristic of the original work. The present volume contains at times a more extended exposition of its subject, yet one not full enough to form a complete review. The limited scope of the work must necessarily prohibit that, since modern surgery exhaustively treated cannot be compressed into a single volume.

The expert in surgery will still use the book as a convenient summary, which, although not always complete, will, at least, present an interesting résumé.

THE BOSTON

Medical and Surgical Journal

THURSDAY, JANUARY 3, 1901

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

MDCCC — MCM.

WITH the beginning of the new century it is natural to review the changes which have taken place since the opening of the century just past, and the physician asks himself what changes have taken place in his own profession during the last one hundred years, and whether these changes have been commensurate with those in other sciences.

One of the great changes which has taken place is in our knowledge of the causation of disease. Not only do we refer many diseases to their origin in germ growth, but this discovery has helped to foster an entirely new variety of medical practice. Preventive medicine was practically unknown one hundred years ago. Our boards of health would probably at that time have been looked upon as meddlers with the individual rights of the profession. Today they are considered not only most important helpers in the prevention, but also in the treatment, of disease.

With the science of the prevention of disease has come in a whole series of new weapons with which to fight it, in the form of disinfectants. Some of these materials were used earlier, but in an uncertain, tentative manner, whereas now we realize more exactly how to use them and how much they may be expected to accomplish. The fires which our ancestors used to burn in the streets to dispel the plague we still use for disinfection, but in a more orderly and usually a less destructive manner.

The department of preventive medicine is but one of a whole series of specialties into which the science of medicine has been divided, and each one of these many specialties has its instruments of precision, many of which were unknown even fifty years ago. The ophthalmoscope is but one in a long list of such new instruments. The compound microscope has opened up a new anatomy and a new pathology. The stethoscope has enabled the physician to use the sense of hearing, which aided the physician of long ago but little, in determining the pathological processes going on under the surface. Electricity has helped still further to show matters which were hidden to the eyesight. What would have been thought of the physician who had dared to foretell, at the beginning of the nineteenth century, that before its close we should be able to see through the integument the broken bones beneath and to mechanically picture them?

Hardly a discovery in the whole range of physics and science but has added something to the practice of medicine. Photography plays its part in the recording of cases. The general use of rubber has contributed widely to the variety of the instruments which are today at the physician's command. Chemistry has not only added materially to our knowledge of the human frame, but has rendered the exhibition of drugs a matter of greatest simplicity. The products of petroleum have practically done away with rancid ointments of previous days, and synthesis has added a series of remedies which are not merely an addition to our pharmacopeia, but an addition to our therapeutics as well.

One has but to mention ether, antisepsis, x-rays, the compound microscope, the clinical thermometer, the stethoscope, the ophthalmoscope and the other instruments for showing morbid conditions previously beyond the reach of vision, the use of active principles instead of crude drugs, the subcutaneous syringe, the use of manipulation instead of brute force in the reduction of certain dislocations, to show how great has been the advance, not merely in the investigation, but in the treatment of morbid conditions, and this list is so far from complete that every one who reads will be able to suggest some important additions. To the physicians of a hundred years ago the physician of today would seem like a magician.

Having indulged in this brief but gratifying enumeration, let us as a profession not forget that *noblesse oblige*, that privileges and advantages imply correspondingly increased responsibility.

UNDERPAID PHYSICIANS OF PUBLIC INSTITUTIONS.

IT will be generally admitted that the life of physicians connected with insane hospitals has its very decided drawbacks. It is an isolated life; there is small possibility for the various social enjoyments which add to the variety of existence beyond institution walls; there is, furthermore, the inevitable limitation which surrounds men who are, in great measure, cut off from the companionship and stimulus of daily contact with fellow-workers. However we look at it, life at an institution entails a continual sacrifice of much that the ordinary man regards as essential to his enjoyment and well-being. In view of this fact it is noteworthy and somewhat remarkable that the State, whose faithful servants these men are, is quite willing to accept their services for a remuneration which is often beneath the value of their work, and which would be regarded as niggardly in many other employ-

ments. It is clear that the work of a superintendent, for example, of a large hospital for the insane is as arduous as one can well conceive. Not only are high qualities of mind demanded for the intelligent control and treatment of a difficult class of patients, but he must also combine with this technical skill an unusual degree of executive ability, in order to manage properly the mere routine of institution work. It is, therefore, simply a matter of justice that the services of such men should be properly recognized. We are glad, in this connection, to call attention to the report of the consulting staff of the Danvers Insane Hospital, recently published in the twenty-third annual report of the institution. After alluding to certain deficiencies capable of reform, the consulting staff brings up the pertinent and important question of the lack of permanency in the office of superintendent. It appears that since 1882 five superintendents have served, and that in the words of the report, "Each of these gentlemen resigned his connection with our asylum on account of the inducements offered him to better his material position elsewhere — inducements that probably no one of them would have felt justified in refusing. . . . The State of Massachusetts is amply able, and should be willing, to give the chief officer of the asylum a separate residence and a salary of at least four thousand dollars. And until it does this it will be liable to lose, one after another, from its servcie men whose abilities are unquestionable and whose experience is invaluable, thus depriving the institution that parts with them of the advantage of a settled policy, and greatly embarrassing the carrying out of plans that take much time for their full development."

With these statements we are in entire agreement. The time has certainly come for the State through its legislators to take such action in the matter that an adequate remuneration for this type of service be at once provided.

MEDICAL NOTES.

A BEQUEST OF ONE HUNDRED THOUSAND DOLLARS TO AN INSTITUTION FOR FEEBLE-MINDED. — It is reported that a bequest of $100,000 has been made to the New Jersey Training School for Feeble-Minded Children at Vineland, N. J., by Thomas H. Vinter, executor of the Maxham estate. The legacy will pay off all obligations and give the institution a cash balance of about $60,000.

LEPERS IN THE PHILIPPINES. — It is estimated that there are at present about 30,000 lepers in the archipelago, most of them being in the Visayas. The disease is supposed to have been introduced in 1633 from Japan. A commission is now engaged in selecting a suitable island or group of islands for the isolation of all lepers.

ARSENICAL POISONING OF BEER. — Arsenical poisoning in beer was the topic of chief interest at the opening session of the convention of the American Chemical Society recently held in Chicago, the discussion growing out of the recent wholesale poisoning in England. One speaker charged the brewers with wilfully introducing into beer an arsenical antiseptic to prevent the fermentation of the beverage from progressing too far.

ENCOURAGING REPORT REGARDING YELLOW FEVER AT HAVANA. — A recent report of the Havana Sanitary Department is more encouraging than any report since June. No Americans are sick with the disease. The 17 cases under treatment December 27th were all Spaniards, recently arrived in Cuba, and are being cared for in Spanish hospitals.

THE "PHILADELPHIA MEDICAL JOURNAL." — According to the *Medical News*, with the opening of the New Year, Dr. George M. Gould will retire from the editorial management of the *Philadelphia Medical Journal*, and the duties he has so ably carried on will be assumed by Dr. John Hendrie Lloyd and Dr. Julius L. Salinger.

SMALLPOX IN WASHINGTON. — Ten cases of smallpox, more virulent than the epidemic of last year, were reported December 26th. The disease is supposed to have been brought from Maryland by a negro.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, January 2, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 158, scarlatina 41, measles 56, typhoid fever 15.

THE OPENING OF THE NEW BUILDING OF THE BOSTON MEDICAL LIBRARY. — The new building of the Boston Medical Library Association will be opened Saturday, January 12th. The exercises will consist of addresses by the president and librarian of the association, and remarks by the president of the Massachusetts Medical Society; Dr. William Osler, of Johns Hopkins Medical School; Dr. John S. Billings, of the New York Public Library; Dr. H. C. Wood, of the Philadelphia College of Physicians, and Dr. H. P. Walcott, acting president of Harvard University. Communications are also expected from one or two other representative members of the profession.

CAMBRIDGE, MASS., STATISTICS. — The recent annual report of the Cambridge Board of Overseers of the Poor gives among others the following statistics: The city physician has made 862 visits upon 462 outside patients, and 1,642 visits upon 179 patients at the City Home. There have been 14 deaths at the institution and 37 deaths outside. The total expenses for outside aid, city home and city farm have been $78,574, and total receipts for same have been $5,973, making a net cost of $72,601 for the care of the poor, which is an increase of $7,840 over the previous year, caused very largely by the greater number of insane patients supported during the past year.

FOUR CENTENARIANS. — Adna A. Treat, born in Hartford, Conn., on April 7, 1797, died at Denver,

Col., on the 9th of December, at the age of one hundred and three years and eight months. James Reed, of Portsmouth, N. H., who celebrated his one hundred and fourth birthday December 9th, has died from the infirmities incident to old age. James A. Nichols, one hundred and eight years of age, died in Harwich, Mass., last week; he was a Welshman. Mrs. Mary Cullen, the oldest woman in Maine, died last week at the age of one hundred and five years, two months and five days. She was born in New Brunswick.

UNDRAINED LAND A MENACE TO THE PUBLIC HEALTH. — At a recent meeting of the Cambridge Medical Improvement Society, it was voted that the danger to the public health demanded the immediate reclamation of the undrained area between Arlington, Somerville, Belmont and Cambridge. United action on the part of the cities and towns interested was urged. A committee was appointed to concur with one already at work, to bring about the desired result.

HOSPITAL FOR TUBERCULOSIS IN BROOKLINE, MASS. — Dr. H. L. Chase and Dr. F. P. Denny have submitted a report relative to the establishment of a hospital for tuberculosis in Brookline. The selectmen of the town have been particularly interested in the equipment and conduct of this hospital and the report of Dr. Chase and Dr. Denny will do much toward influencing them as to the feasibility of establishing some institution of this character.

COLLECTION OF MEDICAL MEDALS. — Dr. H. R. Storer, of Newport, has presented to the Boston Medical Library Association his valuable collection of medical medals. It numbers about 2,300 examples, and is, we understand, the third largest collection in existence. It is to be known as the "D. Humphrey Storer Collection of Medical Medals." Dr. Storer's son, Dr. Malcolm Storer, is to be the curator.

NEW LABORATORY ACCOMMODATIONS FOR THE BROOKLINE, MASS., BOARD OF HEALTH. — The bacteriological laboratory, the work of which has up to this time been considerably handicapped for want of sufficient room, is about to be established in the new public building, in much more commodious quarters. The laboratory has already proved of very great service to the physicians of Brookline.

PROPOSED SANITARIUM FOR TUBERCULOSIS IN MAINE. — An organization to be known as the Maine State Sanitarium Association has recently been formed by prominent citizens of the State. The object of the association is to provide an institution in the Maine woods as a hospital for consumptives. It is proposed to request an appropriation from the next legislature to assist in carrying out the work.

PROGRESSIVE ACTION OF NEWTON, MASS., BOARD OF HEALTH. — The Health Board of Newton has asked the co-operation of the School Board in securing cultures from the throats of 1,000 pupils to determine, if possible, what percentage of well persons, who have not been exposed to diphtheria, carry bacilli in their throats.

FREE HOSPITAL BED FOR TECHNOLOGY STUDENTS. — The trustees of the Massachusetts General Hospital have established a free bed for the use of students of the Institute of Technology, Boston, in recognition of the services the Institute has rendered the hospital.

MEETING OF MEDICAL OFFICERS. — The medical officers of the Second Brigade, M. V. M., met recently at the East Armory, Boston. Numerous papers were read, chiefly relating to the exigencies of war.

A BEQUEST TO THE MASSACHUSETTS GENERAL HOSPITAL. — By the will of the late Roger Wolcott $5,000 is left to the Massachusetts General Hospital.

NEW YORK.

THE HILLIARD CASE AT BELLEVUE HOSPITAL. — In the Hilliard case, in which the inquest was held on December 28th and 29th, the coroner's jury rendered a verdict to the effect that the deceased came to his death from asphyxia and fracture of the ribs inflicted by the three accused nurses, pupils of the Mills Training School at Bellevue Hospital. The conclusion of the verdict was as follows: "And we censure the authorities of said hospital for laxity of the methods of the medical service of said pavilion for the insane, which tended to bring about the death of the deceased." As a result of this finding the three men were committed to await the action of the Grand Jury, the bail being increased in each instance from $1,000 to $5,000. The reason for the alleged physical violence was stated to be the refusal of the patient to take food, and the verdict against the accused was based principally on the testimony of Thomas Minnock, who explained on the witness stand that he had feigned insanity in order to get into the pavilion for the purpose of writing some articles for a newspaper. The counsel provided by Mr. Mills for the accused did not put any witnesses on the stand, stating that the testimony for the defence would be reserved for the Criminal Court.

DISMISSAL OF NURSES AT BELLEVUE HOSPITAL. — After an investigation, Commissioner of Charities Keller has dismissed three male nurses, and suspended six others, employed in the insane and alcoholic wards of Bellevue Hospital, on the ground of brutality and neglect. The three discharged men were arrested on the charge by Coroner's Physician Donlon of having been instrumental in causing the death of Louis Hilliard, an insane patient, and were afterwards released on bail furnished by Ogden Mills, a son of the founder of the Mills Training School for Male Nurses connected with the hospital. In consequence of his investigation the commissioner has placed in charge of the wards mentioned Dr. Louis Schultz, medical inspector in the Department of Public Charities. The State Board of Charities has also taken the matter up, and instituted an inquiry.

Seventy-five Thousand Dollars to a Christian Science Church. — During the contest of the will of Miss Helen C. Brush, who died in July last, bequeathing the bulk of her property of $75,000 to the "First Church of Christ, Scientist," several Christian Science healers have made statements under oath which attracted the special attention of the Health Department and are likely to lead to prosecutions in the future. Among these are the following: That it takes a fee of $100 and a two weeks' course of training for a person to become qualified to heal; that healers never report cases of contagious disease to the department, because it is contrary to the rules of their church; and that the physician who signed the certificate of death in Miss Brush's case acknowledged having signed a certificate in a case which he never saw. This physician, whose card bears the inscription, "Charles Griffin Peace, M.D., D.D.S., C.S." (standing for Christian Science), testified that he was still a member of the Medical Society of the County of New York. He also stated that he had given up the practice of medicine since 1898, but still continued to practise dentistry.

Smallpox. — There have been very few new cases of smallpox in the last two weeks. Dr. Blauvelt, chief of the Division of Contagious Diseases of the Health Department, states that since the first case was discovered on November 5th there have been reported 84 cases of the disease in the Borough of Manhattan, 2 in Brooklyn and 5 in the Bronx, and that only 3 of them have proved fatal. No cases have occurred in the other two boroughs of the city. On December 28th there were still 61 smallpox patients remaining in the hospital on North Brother Island. Over 50,000 persons in Manhattan have been vaccinated by the inspectors of the department, and fully 80% of those had never before been vaccinated. In consequence of the general need of vaccination in the community the Board of Estimate and Apportionment has been asked to make a special appropriation for the payment of 150 additional vaccinators for the first three months of 1901, at the rate of $100 a month.

Electrical Cooking. — At the dinner at the last meeting of the Medical Association of the Greater City of New York, through the kindness of Mr. L. Le Bailly, a friend of Dr. Achilles Rose, the members had the opportunity of practically testing the efficacy of electrical cooking. By means of the Cary electric broiler steaks are done to a turn in five minutes, chops in two and a half minutes, quail in four minutes and sliced bacon in two minutes; the almost equal rapidity with which they were disposed of showed how highly the viands were appreciated.

Gift of $75,000 to New York Eye and Ear Infirmary. — Wm. C. Schermerhorn, second vice president of the New York Eye and Ear Infirmary, has presented to that institution $75,000 for the construction of a pavilion for ear patients. The gift was made in consequence of a perusal of the advance sheets of the annual reports of the infirmary, which direct attention to the urgent need of such a building. In the year past an unusual number of serious cases have presented themselves, and during the last five months 200 mastoid operations have been performed.

Formal Opening of Cornell Medical School. — The sumptuous new building of the Cornell Medical School, on First Avenue, opposite Bellevue Hospital, the gift of Col. Oliver Payne, was formally opened and dedicated on Saturday afternoon, December 29th. Addresses were made by President Schurman, of Cornell University, and Governor Roosevelt, and by Dr. Lewis A. Stimson, professor of surgery, representing the Medical Faculty; after the exercises there was a reception in charge of Prof. Wm. M. Polk, dean of the faculty.

Purchase of Plant of Flatbush Water Company. — The Board of Estimate has decided to purchase by condemnation proceedings the plant of Flatbush Water Company, of Brooklyn, valued at $100,000. This company has for some years supplied the residents of the Flatbush district with water, and its contract with the city expired on December 31st. The supply is obtained from driven wells and the system includes several miles of mains.

Hospital for U. S. Marine-Hospital Service. — It is announced that the Treasury Department has in contemplation the construction of a new three-acre island, to be connected by a bulkhead with Ellis Island, in the harbor, and on this it is purposed to build a hospital for the United States Marine-Hospital Service, to take the place of the present institution on Staten Island, which has been found too inaccessible.

Dismissal of Dr. Peter M. Wise. — On December 20th Governor Roosevelt announced that he had dismissed from office Dr. Peter M. Wise, president of the State Commission in Lunacy, on the charge of malfeasance in office. The ground given for this action is the use of his official position by Dr. Wise in the interests of certain financial companies with which he was connected.

Election of Officers, New York Academy of Medicine. — At the annual election of the New York Academy of Medicine, held December 20th, the following officers were elected: President, Dr. Robert F. Weir; Vice President, Dr. Charles L. Dana; Recording Secretary, Dr. John H. Huddleston; Corresponding Secretary, Dr. Louis J. Bishop.

Bequests of the Late Henry Villard. — By the will of the late Henry Villard, which has just been offered for probate, $50,000 each is left to Harvard and Columbia Universities, $10,000 each to the German Hospital and Dispensary and the New York Infirmary for Women and Children, and $5,000 to the Dobbs' Ferry Hospital Association.

Cigarettes and Insanity. — In the trial at White Plains, Westchester County, of young Burnz for the murder of the postmaster of Scarsdale, in

which the defence was insanity caused by excessive cigarette smaking, Dr. Carlos MacDonald, the alienist expert, recently testified that during the past thirty years he had examined 50,000 persons as to their sanity, and that he had never known of a case of insanity brought on by cigarette smoking.

TYPHOID FEVER AT SING SING. — Dr. Irvin, resident physician of Sing Sing prison, has reported to the State Board of Health that the recent outbreak of typhoid fever in that institution was due to a break in the water-supply pipe, in consequence of which the water became contaminated by local sewage.

MEETING OF MEDICO-LEGAL SOCIETY. — At the annual meeting of the Medico-Legal Society, on December 19th, Clark Bell was elected president, and Dr. Albert Bach read a paper on the "Rehabilitation of the Medical Expert."

Miscellany.

A DEATH ASSOCIATED WITH USE OF THE RÖNTGEN RAYS.

IN the *Lancet* for December 8, 1900, a case is reported of a woman of sixty-eight, who met with an accident resulting in a fracture of the left hip. For purposes of diagnosis two x-ray photographs were taken, with exposures of thirty-five and forty-five minutes respectively. These not being deemed satisfactory a third attempt was made, with an exposure of forty-five minutes. Several days after the second exposure an x-ray dermatitis developed which finally resulted in a sloughing ulcer. Several months later the patient died, not having recovered from the effects of the x-rays. The photographing was done by a non-medical, under the general direction of the physician in charge of the case. At the autopsy the wound had lost its slough, but there was little sign of repair. The heart was flabby and the blood vessels degenerated. The coroner's jury in the case returned the following unanimous verdict: "That the deceased met her death from shock and exhaustion following the accident and the effects of the Röntgen rays upon a weakened system. No blame attached to either the medical man or the photographer."

Commenting on the case the *Lancet* says: "With regard to this case it may be remarked that the fact that the friends of the deceased not having been represented by expert evidence detracts somewhat from the value of the inquiry. It was admitted that no note was made of the time of the exposure, the distance of the tube from the plate, and other details that cannot safely be left to the memory. From the evidence it is clear that a burn resulted from prolonged exposure to the focus-tube, probably from the third exposure of forty-five minutes on April 27th, as the rash appeared seven days after that date. However, the fact that the first exposures were not followed by dermatitis during the thirteen days that elapsed does not absolve those exposures from all blame. It is reasonable to assume that the degenerative changes in the body of the deceased were indirect factors in the causation of the burn just as they were in the fracture of the hip. Unfortunately, for reasons already stated, the full details of the exposures are not available. At the same time we are told of one important differing condition of experiment — namely, that the surface of the body was not protected by clothing on the third exposure, the one from which the damage in all probability resulted. No mention was made of the crucial point of the distance of the focus-tube from the skin. As regards the responsibility of a medical man who engages a non-medical man to take a Röntgen photograph the matter is not advanced by this case. The fact that the patient consents to the photography can hardly absolve the medical attendant. If the latter hands over the operation to a non-medical man it is a question how far he is relieved of responsibility. A chemist is responsible for errors in dispensing a prescription, but he is licensed to practise pharmacy, whereas the electrical or photographic worker with the rays has no such recognized and tested legal status. If the non-medical photographer had undertaken the case for the local hospital what would have been the position of the committee of that institution in the matter? On the other hand, the employment of a medical Röntgen ray expert would clearly absolve a medical man of further responsibility. Any medical operator must have hesitated to expose to the rays for forty-five minutes an old lady who had been laid up for five or six weeks with a broken hip. It seems undesirable, moreover, that female patients should be submitted to the manipulation of instrument makers and other non-medical workers with the rays."

Correspondence.

TYPHOID FEVER *VS.* APPENDICITIS.

BOSTON, December 26, 1900.

MR. EDITOR: — The wide prevalence of typhoid fever should be borne in mind in the consideration of acute abdominal emergencies which demand operation; for under a mistaken diagnosis an atypical typhoid may be operated upon as an appendicitis. If the truth were known, I believe it would appear that not a few cases of typhoid fever have been operated upon because pain and tenderness have been prominent symptoms in the early days of the attack. Cases which begin with malaise and a high temperature, and which develop pain and tenderness secondarily, should be scanned with the greatest care. I have recently seen 4 cases in 3 of which my suspicions were first aroused by an early temperature of 103° to 105°. So high a temperature in suspected appendicitis is sufficient always to excite a doubt, for even the severe cases rarely show so high a fever. When constitutional signs are the most prominent, and local the least, abdominal cases demand the most careful investigation and the most conservative treatment. Of the 4 cases 1 proved to be an acute obstruction from a congenital band, — a chronic and incomplete obstruction so aggravated during the early days of typhoid by the distention of the small intestine as to become acute and complete. The second case marked by high temperature and abdominal tenderness, proved to be a simple febricula dependent upon an injury in the foot-ball field in an overtrained and sensitive boy. The third, beginning with malaise and high temperature, presented, on the third or fourth day, a sudden excruciating abdominal pain starting in the epigastrium and becoming localized in the right iliac fossa, but without local physical signs. It proved to be a typhoid of the severest type, and is now in its third week. The fourth patient, a boy of eleven, had

been prepared for operation for a second attack of acute appendicitis. The symptoms were headache, malaise, very high temperature, with later development of general abdominal tenderness without pain. The attending physician and the surgeon had considered the possibility of typhoid, but were not convinced that appendicitis was not present. I advised against operation on the ground that it was not appendicitis, and asked that a medical man be consulted. The consultant agreed with the others that the disease was probably appendicitis, but of a type which did not at that time demand operation. I could never make myself believe that the appendix was diseased, and took with extreme reluctance the great responsibility of opposing operation. The disease proved to be a typical typhoid of unusually severe type. The tenderness lasted a number of days. The temperature has been a sustained high one. There have been several hemorrhages, and at present the child has pneumonia.

The dangers of a surgical operation performed in the course of typhoid are great, as has been shown by the excessive mortality in the surgical emergency occurring during this disease. I do not now refer to that terrible emergency of the disease, perforation of the typhoidal ulcer, but to such complications as gall-bladder and other indirect infections; to emergencies not in the least dependent upon the disease, such as strangulated hernias and other external and accidental complications. The consequence of an error in diagnosis may be extremely unfortunate for the patient, however desirable the removal of an appendix in health may be. For the surgeon there can be no greater mortification than that which he feels when a normal appendix is found among intestines showing unmistakable signs of typhoid fever. Even with the greatest care this mistake may be made. It is humiliating only when the diagnosis has been so hasty, not to say careless, that typhoid has not even been thought of.

Yours respectfully,

M. H. RICHARDSON, M.D.

KIRKES' PHYSIOLOGY.

KING'S COLLEGE, LONDON, December 7, 1900.

MR. EDITOR: My notice has been drawn to the reviews published in your issue of November 8, 1900, of the two rival editions of "Kirkes' Physiology," and I must thank you and your reviewer for the determined stand you have made in the interests of international honesty. I have also seen Dr. Warren Coleman's reply, published on November 22, 1900.

Your reviewer mentions specially the figures of blood crystals as having been "lifted" from my edition without any acknowledgment. These figures occurred in the "Handbook" before I undertook the editorship of the authorized version, and so far Dr. Warren Coleman might appear to score a point. The facts are, however, (1) that Messrs. Wood have never acquired any rights at all from the English owners and editors of the book; (2) when the work was under the charge of Mr. Morrant Baker and Dr. Vincent Harris, an edition authorized by the proprietors of the book was published by Messrs. Blakiston; (3) that Messrs. Wood have continued to publish their edition in spite of repeated remonstrances, and that their use of Mr. Baker's and Dr. Harris's names and of the materials introduced by those gentlemen is as improper as the use of materials introduced by me.

There are, however, other figures which have been pilfered from those which I have added to the book (Fig. 167 A and Fig. 340 of Wood's sixteenth American edition). The ethics of the proceeding are the same whether "lifting" has occurred in one part of the book or in another. The other statements contained in your reviewer's note are correct, and Dr. Warren Coleman has made no attempt to answer these, obviously because he is unable to deny their truth.

I remain yours faithfully,

W. D. HALLIBURTON.

METEOROLOGICAL RECORD

For the week ending December 22d, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Melrose	12,962	4	1	—	—	—	—	—

Deaths reported 2,518; under five years of age 735; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 584, acute lung diseases 401, consumption 294, diphtheria and croup 129, typhoid fever 65, diarrheal diseases 30, scarlet fever 23, whooping cough 17, cerebrospinal meningitis 10, measles 8.

From whooping cough New York 8, Pittsburg, 3, Philadelphia and Baltimore 2 each, Boston and Worcester 1 each. From cerebrospinal meningitis New York 5, Pittsburg, Lowell, Somerville, Salem and Newton 1 each. From scarlet fever New York 10, Boston 5, Philadelphia 4, Pittsburg, New Bedford,

Brockton and Malden 1 each. From measles New York 7, Boston 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending December 8th, the death rate was 17.7. Deaths reported 3,937: acute diseases of the respiratory organs (London) 400, diphtheria 98, whooping cough 91, fever 55, measles 51, scarlet fever 35, diarrhea 33.

The death rates ranged from 11.5 in Croydon to 22.1 in Hull: Birmingham 18.7, Blackburn 16.0, Bradford 15.0, Brighton 15.5, Cardiff 11.8, Derby 16.9, Gateshead 16.7, Halifax 16.6, Leeds 16.7, Liverpool 21.9, London 17.5, Manchester 20.6, Newcastle-on-Tyne 16.9, Nottingham 19.3, Portsmouth 13.6, Sheffield 21.5, Sunderland 21.2, Swansea 15.3, West Ham 14.4.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING DECEMBER 29, 1900.

R. E. LEDBETTER, assistant surgeon, detached from the "Mononganela" and ordered to the "Constellation."

C. R. BURR, assistant surgeon, order of December 19th revoked; ordered to resume duties on the "Mononganela."

C. P. BRADLEY, medical director, commissioned medical director from May 31, 1900.

P. FITZSIMONS, medical director, commissioned medical director from November 19, 1900.

W. H. JONES, medical inspector, retired, died at Bethlehem, Pa., December 13, 1900.

S. S. RODMAN and J. M. BRISTER, assistant surgeons, appointed from December 14, 1900.

C. H. BARBER, surgeon, commissioned surgeon from June 7, 1900.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE FOR THE FOURTEEN DAYS ENDING DECEMBER 27, 1900.

PURVIANCE, GEORGE, surgeon. To report at Washington, D. C., for temporary duty. December 14, 1900.

SAWTELLE, H. W., surgeon. Granted leave of absence for thirty days from January 20, 1901. December 18, 1900.

WHITE, J. H., surgeon. Bureau letter of October 11, 1900, granting Surgeon White leave of absence for thirty days, amended so that said leave shall be for twelve days only. December 18, 1900.

CARRINGTON, P. M., surgeon. Granted leave of absence for thirty days on account of sickness. December 18, 1900. Relieved from duty at Washington, D. C., and directed to proceed to Fort Stanton, N. M., and assume command of the service, relieving Passed Assistant Surgeon J. O. COBB. December 18, 1900.

COBB, J. O., passed assistant surgeon. Relieved from command of service at Fort Stanton, N. M., and directed to report to medical officer in command for duty. December 20, 1900.

ROSENAU, M. J., passed assistant surgeon. Upon completion of duty at Paris, France, to rejoin station as director of Hygienic Laboratory, Washington, D. C. December 19, 1900.

MCMULLEN, JOHN, assistant surgeon. Relieved from duty at Tortugas Quarantine and directed to proceed to Savannah, Ga., Quarantine Station for temporary duty. December 15, 1900.

KORN, W. A, assistant surgeon. Granted leave of absence for seven days from December 24th. December 17, 1900.

OLSEN, E. T., junior hospital steward. Granted leave of absence for ten days from December 23d. December 7, 1900.

MCINTOSH, W. P., surgeon. To proceed to Columbus, Ga., for special temporary duty. December 23, 1900.

DECKER, C. E., assistant surgeon. Granted leave of absence for fourteen days on account of sickness. December 24, 1900.

BAHRENBURG, L. P. H., assistant surgeon. Relieved from duty at the Immigration Depot, New York, N. Y., and directed to proceed to Manila, P. I., and report to the chief quarantine officer for duty. December 27, 1900.

DUFFY, FRANCIS, acting assistant surgeon. Granted leave of absence for six days from December 29th. December 24, 1900.

LINLEY, W. J., acting assistant surgeon. Granted leave of absence for thirty days. December 22, 1900.

APPOINTMENT.

A. C. FRASER, of Wisconsin, appointed acting assistant surgeon for duty at the port of Manitowoc, Wis. December 17, 1900.

SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—The annual meeting of the society will be held at the Medical Library, 19 Boylston Place, on Monday, January 7th, at 8.15 P. M.

Papers: Dr. Joel E. Goldthwait, "Diseases of the Spine of Non-tubercular Origin."

Dr. Elliott G. Brackett: "Attitudinal Strains of the Spine."

Dr. Robt. W. Lovett: "The Neurasthenic Spine."

Dr. John Dane: "Thoracic Pressure in Spinal Supports."

Dr. Fred'k J. Cotton: "A New Method of Application of Plaster Jackets."

Dr. J. S. Stone: "Rhachitic Spine."

Election of officers at 9 P. M.

ARTHUR K. STONE, M.D., *Secretary*, 657 Boylston Street.

RECENT DEATHS.

GEORGE G. TARBELL, M.D., M.M.S.S., died December 28th, at the age of fifty-nine years.

EDWARD A. SMITH, M.D., of New York, died on December 11th. He was born in Stonington, Conn., in 1830, and was a graduate of the Medical Department of the University of Pennsylvania. He at one time served as assistant physician in the State Insane Asylum at Worcester.

ULYSSES H. BROWN, M.D., a distinguished eye and ear specialist of Syracuse, died suddenly in New York, on December 27th, at the age of forty-eight.

ISAAC WARD FERRIS, M.D., of Mount Vernon, N. Y., died on December 25th, in the sixty-first year of his age. He was a son of the late Chancellor Ferris, of the University of the City of New York, and was a graduate of the University and of the Yale Medical School.

BOOKS AND PAMPHLETS RECEIVED.

Thirtieth Annual Report of the Central State Hospital of Virginia (Petersburg, Va.) for the Fiscal Year ending September 30, 1900.

The Treatment of Fractures. By W. L. Estes, A.M., M.D., Director and Physician, etc., St. Luke's Hospital, South Bethlehem, Pa. New York: International Journal of Surgery Co. 1900.

Sanity of Mind: A Study of its Conditions and of the Means to its Development and Preservation. By David F. Lincoln, M.D. New York: G. P. Putnam's Sons. London: The Knickerbocker Press. 1900.

Refraction and How to Refract, including Sections on Optics, Retinoscopy, the Fitting of Spectacles and Eyeglasses, etc. By James Thorington, A.M., M.D. Second edition. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1900.

Comparative Physiology of the Brain and Comparative Psychology. By Jacques Loeb, M.D., Professor of Physiology in the University of Chicago. Illustrated. New York: G. P. Putnam's Sons. London: John Murray. 1900.

Therapeutics: Its Principles and Practice. By Horatio C. Wood, M.D., LL.D. Eleventh edition, remodelled and in greater part rewritten. By Horatio C. Wood, M.D., and Horatio C. Wood, Jr., M.D. Philadelphia and London: J. B. Lippincott Co. 1900.

The Medical Examination of Life Insurance and its Associated Clinical Methods, with Chapters on the Insurance of Substandard Lives and Accident Insurance. By Charles Lyman Greene, M.D. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1900.

A Compend of Diseases of the Skin. By Jay F. Schamberg, A.B., M.D., Professor of Diseases of the Skin, Philadelphia Polyclinic and College for Graduates in Medicine, etc. Second edition, revised and enlarged. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1900.

Diseases of the Nervous System: A Textbook for Students and Practitioners of Medicine. By H. Oppenheim, M.D. Authorized translation by Edward E. Mayer, A.M., M.D. First American from the second revised and enlarged German edition. Illustrated. Philadelphia and London: J. B. Lippincott Co. 1900.

Textbook of Histology, including the Microscopic Technic. By Dr. Philip Stöhr, Professor of Anatomy at the University of Würzburg. Third American from eighth German edition. Translated by Dr. Emma L. Bilstein. Edited with additions by Dr. Alfred Schaper. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1900.

Abstract of Report on the Origin and Spread of Typhoid Fever in U. S. Military Camps during the Spanish War of 1898. By Walter Reed, Major and Surgeon, U. S. Army, Victor C. Vaughan, Major and Division Surgeon, U. S. Volunteers, and Edward O. Shakespeare, Major and Brigade Surgeon, U. S. Volunteers. Washington. 1900.

Obstetric Clinic. By Denslow Lewis, Ph.C., M.D., Professor of Gynecology in the Chicago Polyclinic, etc. A Series of Clinical Lectures on Practical Obstetrics delivered to Students and Practitioners in Cook County Hospital, Chicago, together with Remarks on Criminal Abortion, Infanticide, Illegitimacy, the Restriction of Venereal Diseases, the Regulation of Prostitution and other Medico-Sociologic Subjects. Chicago: E. H. Colegrove. 1900.

Original Articles.

A SHORT ACCOUNT OF THE RECENT INTERNATIONAL MEDICAL CONGRESS IN PARIS.[1]

BY HENRY BARTON JACOBS, M.D.,
Instructor in Medicine, Johns Hopkins Medical School, Baltimore, Md.; Secretary of the American National Committee.

In whatever I may have to say I am largely forestalled by the excellent reports of the congress published in the *Boston Medical and Surgical Journal* during August, September and October.

The recent International Medical Congress is numbered thirteen in the series of International Congresses that have been held. The first, like this last, met in Paris during an exposition year. French physicians were contemplating arrangements for the annual gathering of their National Medical Association in 1867, when it occurred to the executive committee that it might be agreeable and becoming to ask a number of foreign physicians likely to visit the exhibition to attend the sessions of the association. Forthwith, invitations were sent out and several foreign vice presidents appointed. Fully 500 gentlemen from outside of France responded to this cordial request. The meeting was such an eminent success that Dr. Pantaleoni, of Italy, suggested it should be considered the first of a series of meetings held from time to time, to be known as the International Medical Congress. The suggestion met with universal favor, and accordingly it was voted that the second congress should meet in Italy in honor of Dr. Pantaleoni's nationality, two years hence, in 1869. Rome at this time was still under papal supremacy, so Florence was selected, that there might be no embarrassment to Protestant nations. Then came the Franco-Prussian War, and we find the third meeting postponed until 1873 at Vienna, following which the fourth, fifth, sixth and seventh occurred at intervals of two years at Brussels, Geneva, Amsterdam and London, respectively. All proved interesting to a constantly increasing number of attendants, though until that of 1881, in London, the American profession had taken no signal notice of their occurrence. Nearly every one was marked by the announcement of some important step in medicine, so that a study of the proceedings of these congresses during their existence will acquaint one with the main steps in the progress of medicine through these years. I call to mind that of 1875, at Brussels, when the transmissibility of puerperal fever at last became so fully recognized that a series of resolutions were passed recommending the abandonment of large lying-in hospitals; that of 1879, when Lister, with his fresh views upon the significance of antisepsis, was the hero of the hour.

With the meeting in London in 1881 begins the real modern conception of medicine from the new etiological point of view — the importance of the exclusion of pathogenic parasitic life to the health of the individual. Each congress since has left a more or less distinct footprint in the evolution of this conception.

Following London were the meetings at three-year intervals at Copenhagen in 1884; Washington, 1887; Berlin, 1890; Rome, 1894; Moscow, 1897, and now Paris, 1900.

Of those preceding this last I have little to say; for many reasons, not all of which are wholly creditable to our American profession, the meeting in Washington in 1887 was the least satisfactory of the series, while that in Berlin in 1890 was one of the most satisfactory — all the world was there, eager, expectant, to see and to listen to the man who might be about to proclaim to all future generations the same relief in that great devastating disease of tuberculosis which Jenner a little less than a hundred years before had made possible in the great curse of his time. Koch spoke, the world hearkened, but, alas, time has not yet proven that his words were prophetic.

Of no less interest were the meetings in 1894 in Rome and 1897 in Moscow. Each denotes an era of progression, the former having for its salient feature the full recognition of the possibilities of serum therapy, while at Moscow, as has been well said, the world first awoke to an appreciation of the high state of Russian medical science.

Before adjournment in 1897, Paris was selected as the next meeting place.

Professor Lannelongue, with Dr. A. Chauffard as secretary, and Dr. Du Flocq as treasurer, and an executive board numbering some of the proudest names in French medicine today, such as Bouchard, Brouardel, Raymond and Roux, went diligently to work to inaugurate the congress of this year, that which should be destined to mark the medicine of the civilized world at the end of the nineteenth century. With what success he accomplished his purpose I shall but vainly, I fear, be able to tell you. Whatever the success, however, I am sure he would be the very first to share it with his indefatigable colleagues, especially the secretary, Dr. Chauffard, and the treasurer, Dr. Du Flocq.

Perhaps a word in regard to these three men as I saw them may not be out of place. I am sorry I have not good photographs to show you. They convey so much better impressions than mere words, but I have a newspaper print of President Lannelongue which will convey slightly, perhaps, an idea of his personality. It is almost libellous to show it; it does the man such an injustice.

Lannelongue is about sixty years old, heavily built, of florid complexion, with large, laughing, keen brown eyes, set wide apart, an attractive smile; full of dignity and composure, yet alert and vigorous, professor of surgical pathology in the Faculty of Medicine and honored with the distinction of being a member of the Institute as well as of the Academy of Medicine. One rare faculty he possesses — that possessed to such an eminent degree by the late Mr. Blaine — the faculty of remembering face and name of any individual introduced to him. This alone made him a most popular and valuable head, for his geniality and readiness to recognize even the smallest of those presented could but attract and encourage good feelings.

Chauffard is young, perhaps thirty-eight, slight, wiry, active, nervous, full of executive ability, not forgetful of the minutest details. To him, perhaps, more than to any one else, is due the perfect organization of the congress, and for his efforts he has been decorated with the insignia of the Legion of Honor.

Du Flocq, the treasurer, is also young, genial, kind, honest, thoughtful of every one, methodical to a degree, the man to whom you would trust your all.

Fortunately, no fixed rules, except of their own making, confined these men in their undertaking, and

[1] Read before the Boston Society for Medical Improvement, December 10, 1900.

they were able to organize the congress along their own lines. The first move, so far as could be seen at this distance, was the selection from each nation of the world of a physician who should become chairman of the national committee of his country, he naming this committee from the leaders of the profession. I need not tell you that Professor Osler of Baltimore was asked to fill this office in America, and that he named the presidents of the leading national associations as his committee.

As in the preceding congresses at Moscow, Rome and Berlin, the numbers responding, especially among foreigners, were very gratifying, and on Sunday, the 5th of August, as many as 6,200 representatives from thirty-four nations of the world had registered their attendance, together with some 3,000 wives, sisters and daughters, an attendance, therefore, on this day of nearly 10,000 persons. Nor is it to be wondered at: not only was it a congress at the end of a century, but it was in connection with a great international exposition of arts and sciences, and, moreover, held in Paris — Paris with its Louvre, its Seine, its Champs-Elysées, its Beaux-Arts, its Notre Dame.

The registration of this large body of people, speaking nearly all the languages of the globe, was done most expeditiously and satisfactorily. In no less a cosmopolitan city would it have been possible. Volunteer students from all nations were stationed behind tables stretched along the arcade bounding the inner court of the École Pratique. Each proclaimed his nationality by a big sign attached to the wall over his head. Each had the subscription list of that nation, and the registration blanks, invitations, tickets, etc., of each subscriber. It all went like clockwork, so careful and painstaking had been the organization.

A glance at these 6,000 names: Two thousand two hundred of them are French, 800 Russian, 600 German, 400 American (that is, from the United States), 300 Italian, 200 British, and notice 108 from Argentine Republic and 43 from Japan. The United States, therefore, stood fourth in respect to numbers, and Great Britain sixth. The latter's low figures are to be easily accounted for by considering the strained political relations of the two countries for the past several years; the Fashoda incident, the warm, ill-concealed, even outspoken sympathy of the English for Dreyfus, and their threats of boycotting the exposition in case he was not pardoned. Then, in their turn, the French caricatures of those sacred to the English hearts, and their pronounced advocacy of the Boer cause.

But why the numbers of Americans should have fallen from 657 present at the tenth congress in Berlin to 412 at the present one is hard to explain. It must be admitted that many in the United States are not believers in the usefulness of International Congresses, while many more perhaps considered that this would be an expensive and uncomfortable year to visit Paris. I am sorry to say I feel that here in New England men were influenced to remain at home by the statements of "Spectator," whose letter appeared in your JOURNAL on March 8, 1900. As I walked the streets of Paris, attended the meetings of the congress, visited the houses of the French, receiving nothing but kindness and courtesy on all hands, I often wondered who this unfortunate individual could be that his life should be cast in such unhappy lines, why perchance he did not leave the hostile shores rather than stay on only to suffer and to complain. How different his letter from those other letters written some seventy years ago by that enthusiastic, lovable young Bostonian, James Jackson, studying in Paris — letters so full of gratitude for the opportunities afforded, so full of affection for the masters with whom he worked, so full of praise of the privileges of living and enjoying Paris, knowing her language and learning from her great teachers — Louis, Andral, and Chomel. Unhappily, the officers of the French Congress saw the letter and were very much hurt, not only that such an one should have been written, but also that it should have had credence in any American town.

But who are the individuals making up these 6,000 names? I will cite but a few examples. Are they the young, the obscure, the unknown? I need not quote those of France; all the well-known men of this generation are to be found there. Germany: Virchow, von Bergmann, Ebstein, Naunyn. Italy: Golgi, Bianchi, Baccelli. Austria: Albert, Danielski, Kaposi. Great Britain: Lister, MacCormac, Dyce Duckworth, Mayo Robson, Lauder Brunton. United States: Jacobi, Janeway, Bradford, Murphy, Keen, Richardson, Weir, Warren. The leaders of medical thought the world over.

The hotel accommodations of the city proved ample, not only to care for the visiting doctors and their families, but also for the thousands of other people attending the Exposition, and prices, too, contrary to the general prediction, were not excessive. I had a very comfortable room in one of the best hotels, near the Vendome Column, for twelve francs a day ($2.40). One could scarce do better here in Boston, even in the midst of summer, and, if one chose the pensions or mere lodging houses, especially in the Latin Quarter, it is remarkable how cheaply one might live. A young friend found lodgment in the most delightful of quarters with the cousin of Victor Hugo, now a charming old gentleman of seventy, who has gathered about him and preserved nearly all of the great novelist's treasures, bric-a-brac, the table upon which he wrote, the ink stand in which he dipped his pen, even the bed in which he slept and the clothes which he wore, and yet in such surroundings and in company of such an intelligent and attractive landlord he paid but three francs a day for his room (sixty cents).

The last ten days of July had been excessively hot both in England and France, but with the advent of August came a cold rain, and throughout the remainder of the summer the weather on the continent of Europe could not have been more delightful. During the week of the congress occasional showers, fresh and cool like the April rains of New England, cleaned the streets and made the necessity of an overcoat at night imperative.

Registration began July 31st, and by noon of August 2d the majority of the members were enrolled. Across the street in the beautiful new part of the medical school each country was provided with a separate meeting place for its national committee and their compatriots. These served as the headquarters of each country where bulletins could be posted or engagements made. This little register kept in the United States room shows the names of many of the American members.

Although the work of the congress was divided

into many sections, the numerous amphitheatres of the medical school, the nearby Sorbonne, and the adjacent hospitals lent themselves most conveniently to their purposes, centralizing the sections for the most part within two or three minutes' walk.

As was admirably appropriate, the dermatologists met at the St. Louis Hospital, where the wards furnished ample resources for the demonstration of many of the most interesting skin affections, and indeed these demonstrations became an essential part of the work of that section. Likewise, the Pasteur Institute was appropriately designated for the Section of Bacteriology and Parasitology, and here Roux, Marmorek, Leveran and others were to be seen constantly in attendance.

The first official business of the congress was the reception by the President of the Republic of the national delegates. These numbered five to ten from each country, and some thirty-four countries were represented. It took place at the Elysée Palace at 10 o'clock on the morning of August 2d. Delegates were bidden to appear in full dress, wearing orders, decorations, etc. For the first time in my life I put on a dress-suit at 9 o'clock in the morning, and I must say I felt much as if I had been out over night. However, this proved one of the most interesting of the official functions of the congress. On arrival at the palace we were ushered into a very large reception room, beautifully decorated in white and gold, and hung with interesting tapestries of the Louis Quinze period. Here we found representatives of other nations gathered. Before the arrival of the President the delegates were grouped together by countries, and then these groups arranged alphabetically in a large semicircle about the room. The United States, under its French name of *Etats Unis*, stood between *Espagne* and *Grande Britagne*. The sight of this array of 200 or 250 men I shall not soon forget. They were for the most part the leaders of the profession in their respective countries, and their countenances and dignified bearing easily denoted their high positions. Many connected with the army or navy were dressed in full uniform, and all possessing decorations of any sort did not fail to wear them. President Lannelongue in the green embroidered coat of the Institute, with red sash and rapier, von Bergmann most resplendent in orders and medals, Sir Wm. MacCormac, Virchow, Reverdin, Zambaca Pacha, are but a few of those who catch one's eye. Promptly at 10 a most distinguished looking butler, if I may call him such, in powdered hair, velvet coat, silk knee breeches, and white stockings announced in a loud voice "le Président de la République." Emile Loubet entered, escorted and followed by the president, secretary and treasurer of the congress, several of his ministers and a small body guard. Thereupon, Professor Lannelongue stepped forward, presented him to the delegates in a short, formal address, to which he immediately replied, expressing his pleasure in greeting so many distinguished representatives from so many countries.

During all this time our neighbors, the Spaniards, magnificent in dress and decorations, whose presence at our very elbows we could not think of without some little degree of embarrassment, inasmuch as we could but wonder how they looked upon us, their recent conquerors, kept up an incessant noisy, excited conversation. Something had gone wrong with them, and not even President Loubet's words could silence them. Such a nation are they for talk. What must the Spanish Parliament have been during the trying days of Dewey's victory and Cervera's defeat!

After the President's general greeting, he proceeded within the circle, giving individual welcome to each state, hearing the names and shaking hands with many of the delegates. Arriving at *Etats Unis* he greeted us most warmly, congratulated us upon our country so pre-eminent in its arts and sciences, and bade us hearty welcome as representatives of one great republic to another. Dr. Warren, who happened to be standing nearest him, in a few fitting sentences, and, I am happy to say, in very good French, thanked him for his welcome. It seemed to be noticeable that there was an earnest desire, not only on the part of all the officials of the congress, but on the part of the President of the Republic as well, to give Americans a particularly cordial greeting, and make them feel at home in France.

The first general assemblage of the congress met in the afternoon of this day in the Salle des Fêtes of the exposition, a tremendous auditorium capable of holding 25,000 or 30,000 people, wonderful to look upon from a structural point of view, hexagonal in shape, with very high dome roof and immense galleries on five sides, with the stage or platform on the sixth. Here were seated the delegates in full dress and uniform, as in the morning. The congress opened with a full military band playing the "Marsellaise," and as the moving strains of this spirited national anthem filled the immense space and one looked down upon the thousands of physicians assembled from all over the civilized world, he could but feel the cold shivering of excitement and emotion creep along his spinal marrow. It was really a moment not to be missed. What matter the words of any individual whether they be heard or not? Here was an occasion when one realized perhaps for the first time what it meant to belong to this great body of workers, assembled here from all corners of the earth to learn of one another for the good of humanity. The President of the Republic was to have greeted the congress, but the recent death of the King of Italy and the consequent official state mourning did not allow him to appear on this public occasion, and one of the ministers of state performed the duty. After President Lannelongue's inaugural address, and a few words from Dr. Chauffard regarding the organization of the congress, representatives were called upon to reply for each country.

Some spoke in French, but as a rule they employed the national language of the country they represented. In the absence of Surgeon-General Sternberg, who had been detained on the Pacific Coast with duties connected with affairs in the Philippines, his official representative, Major La Garde, medical director of the army, in the full uniform of his rank, replied in a few well chosen words for the United States. He first alluded to our national admiration, respect, even reverence for the name of Pasteur, the great figure in modern medicine, a true citizen of France. Others following also touched upon the same subject, but none more gracefully than he.

The representative of Canada, Sir Wm. Hingston, received the great ovation of the day; thunders of applause greeted him as he arose, which died away only to be taken up again and again. What was its significance none of us could think; it was sug-

gested that he stood for the Roman Catholic party of Canada, and so the French of the Old Régime. But later it was said that he had been mistaken for Lord Lister, and the round upon round of applause was intended for that famous man. The mistake might well occur, for both are rather tall, distinguished looking men, with shape of head similar, both wear the same cut of beard, both are very gray, but I am not at all sure that the first explanation is not the correct one.

Following these addresses Professor Virchow, in behalf of Germany, and as the great representative of German medicine, read his paper upon "Traumatism and Infection." Still adhering to his early conceptions, he pleaded for greater attention to pure cell pathology, less for the microbic, and instanced the changes taking place in an extra-uterine fetus, where bacteria are presumably absent. The great size of the hall precluded the possibility of any but those immediately surrounding the speaker hearing his venerable words, and so, although one of the oldest and most eminent of medical scholars of the century was speaking, the audience gradually dwindled away, except those within easy reach of his voice.

On the afternoons of August 6th and 9th the second and third general assemblies were held in the large amphitheatre of the Sorbonne, and a beautiful auditorium it is, with its graceful galleries and fine mural decoration from the hands of France's own Chavannes. Large and enthusiastic audiences greeted the speakers representing the five other favored nations of the world. As I have said, Virchow spoke for Germany at the first assembly. Now followed the paper of Pavlov as representative of Russia; Baccelli, of Italy; Albert, of Austria; Burdon Sanderson, of Great Britain, and Dr. A. Jacobi, of the United States. The latter spoke in French, and was listened to with rapt attention, especially by the Europeans. To our shame it seems to me few Americans stood by our national representative at a time when he was responding to the honor conferred upon us by being invited to speak, and when he was doing such credit to our institutions and men, by telling an audience more or less ignorant of us what we had been, what we had come to be, and what was the great outlook for the future, when eyes now turned to the East should be prone to look to the setting rather than to the rising sun. No address received better attention, and none compared in the applause it evoked. That he spoke plainly, even bluntly, there is no doubt, but that he spoke truly is also beyond question. And he deserves our united thanks for the able and creditable manner in which he represented our country.

Before saying his farewell words Professor Lannelongue announced that it had been decided that the Fourteenth Congress should meet in Madrid in 1903 under the presidency of Professor Calleja, and that in behalf of the younger workers it was voted Ramon y Cajal, of Madrid, be given the Moscow prize of $1,000 for his careful work on the minute structure of the nervous system.

The work of the various sections began on Friday morning, August 3d. I can scarcely attempt even to outline the work here carried on. Each had a long programme which required nearly the whole week, even with morning and afternoon sessions, to complete. If any papers were refused surely the list presented did not show it, and in this lies the great possible criticism of this congress — possibly all general congresses. Instead of abstracts, each full paper should be submitted to committees from each section who, like editors, should sift the chaff from the wheat and allow only those of real merit to be read; but the duty is a delicate one, and probably no country is yet bold enough to undertake this reform. The whole programme included two hundred and sixty reports and more than one thousand two hundred communications. I will only speak of some of the sections I visited.

In the anatomical section important subjects, such as "Topography of the Brain," "The Ascending Tracts of the Cord," "The Formation of the Cortex," were discussed by no less authorities than Waldeyer, Van Gehuchten and His. In the sections of medical sciences the mooted questions of infection and immunity engaged much attention, and, here were to be found the leaders along this line of thought so recently deduced in logical sequence from the developments of preceding years, namely, Grawitz, Buchner, Metschnikoff, Calmette, Rodet, Widal, Chantemesse. Toxins and antitoxins found exponents in Ehrlich and Roux; alimentation in Leube, Ewald, and Le Noir; paludism in Laveran, Grassi, while Behring opened a discussion upon tuberculosis and Borrell upon the parasites of cancer. Baumgarten, Ziegler, Weigert and Marinesco spoke upon inflammation and reparation of tissues.

The discussion upon the pathogeny of gout engaged in by Dyce Duckworth, Ebstein, Le Gendre and others showed how far at variance were still our ideas upon this important subject and how much work was still at hand for the student of physiological chemistry and metabolism.

In no section was the work more thorough or more interesting than that in neurology, presided over as it was by Charcot's successor at the Salpêtrière, Professor Raymond. Here were to be seen the active workers of this intricate branch of medicine — names familiar to you all, Brissaud, Déjerine, Grasset, Marie, Hitzig, Bianchi, Marinesco, Ferrier, Leyden, Krafft-Ebing, Flechsig, and Voisin. A feature introduced at this section, and one most interesting to the members, was a daily clinical demonstration of some subject illustrated by a series of cases brought either from the Salpêtrière or the Bicêtre. The richness of these two hospitals in all forms of nervous disease warrants the statement that these demonstrations were most creditable and instructive.

Surgery, presided over by the venerable but still active Tillaux, was very largely attended, but of the character of the work done I am incompetent to speak. America, so sparingly represented in many other sections, was to be found among the surgical sciences with the names of physicians known to the world. Keen, of Philadelphia, reported his case of ligation of the abdominal aorta; Weir, of New York, suggested a new method of operating in cases of acute appendicitis, and Murphy, of Chicago, spoke upon intestinal obstruction, while Fenger, of Chicago, Young, Cullen, and Gilchrist, of Baltimore, Carl Beck, Palmer Dudley, of New York, and de Schweinitz, of Philadelphia, made themselves heard in their respective branches.

The practical work of French surgeons claimed much attention. Many of their clinics were con-

stantly full of visitors, and here in an informal way surgeons discussed cases and methods, and observed the work of their French brethren.

Particularly full was the clinic of Dr. Doyen, and at the time of my visit I found myself *vis-à-vis* with many of the most eminent and renowned surgeons of the day, watching like students the operations of this man. I almost hesitate to speak of his work. Doyen is perhaps forty years of age, strongly and muscularly built, with high, retreating forehead and deep set eyes. The newspaper cut will give you some idea of his appearance.

The story is that he is owner or part owner of one of the champagne brands, and so a man of very large means. For some years he practised in one of the provincial towns, then as his fame spread and he became more ambitious he moved to Paris, built a hospital in the new part not far from the entrance to the Bois, and there carried on his surgical work. The hospital is a model private institution, with some thirty-five or forty rooms comfortably, even elegantly, furnished, with modern plumbing, heating and lighting. His operating room is at the top of the house, and seems to be very well arranged. In the wall of the room, with door opening outward, is a beautiful sterilizer, whose contents can be reached in a second by assistant or nurse, while above is a fine clock with stop attachments, so that the length of an operation can be accurately timed. Near by are etherizing and recovery rooms, as well as library, museum, and rooms for the demonstration of surgical methods.

In his work Dr. Doyen is ambidextrous, every movement has its purpose, every action tells, but when I say to this audience that I saw him remove a cancer of the breast, clean out the axilla and sew up the wound in exactly *seven* minutes, I am sure you will agree with me that this is not surgery. Surgery, at least in these days, means so much more than mere dexterity in operating; it means deliberation, judgment, care, and especially in such cases as this, *thoroughness*.

After viewing this spectacle of race-track operating we were asked to take places in the next room, where cinematograph pictures of Dr. Doyen performing all sorts of capital operations were reeled off for our instruction, and indeed I am told that no longer is it necessary to cross the ocean to see these interesting representations, that in Chicago in one of the vitascopic exhibits, after a certain hour, ladies are invited to remove themselves, while the gentlemen are regaled with a series of Dr. Doyen's surgical pictures. For the truth of this I cannot vouch, but I know from a truthful gentleman that they are on exhibition in Buda Pesth.

Dr. Doyen is not a member of the Faculty of Medicine of Paris, but that he is treated with consideration, even if not with respect, is shown by the fact that he was allowed to present *seven* different papers in as many different sections of the congress — a résumé of all which, printed by himself, was circulated promiscuously among the thousands of visiting physicians. That he has genius there is no doubt, but that it is mechanical rather than surgical is exemplified by the large exhibition of surgical instruments which he has invented.

The other subject which attracted a great deal of attention was Tuffier's method of operating under spinal anesthesia. Indeed, if one thing rather than another marked the attention of members of this congress it was this subject, and the manner in which it has been tried throughout the world since this meeting demonstrates clearly to my mind, what I perhaps ought not to say above a whisper here in Boston, namely, that there is felt a universal need for a new anesthetic. That in the minds of many surgeons the old have their strict limitations, and a large and increasing class of cases requires something different. This feeling has been evident for some time, as the tendency more and more to local anesthesia has been witnessed. I cannot think that it is a mere fad of the hour, but rather a genuine need, which this reaching out for new means represents. Tuffier seems not to have priority in the matter, but surely he, more than any one else, has called it to the world's attention. He uses the method boldly and maintains there is little or no risk. In the two cases I saw operated upon there was no question about the profoundness of the anesthesia to pain and although one of the patients showed symptoms of collapse with vomiting and sweating, neither symptom was very urgent nor lasted very many minutes. But this subject has been so largely considered in the medical journals within the last few weeks that I will not speak of it further.

If time permits, a word or two about the entertainment of members. Here, also, the death of Italy's king somewhat interfered with the plans proposed. The first general reception in the Luxembourg Palace proved rather a failure on account of one small oversight. Melancholy Jaques would have arranged it better, for he would have remembered that men and women must have their exits and their entrances. The programme was novel and should have been most delightful, the amount of refreshments would have done for a whole army corps, so lavishly had everything been provided, but as it was a cold night people found it too dangerous to wander about the beautifully illuminated gardens, and so the rooms of the palace became overcrowded, and the fine main stairway with its double row of faultlessly uniformed cuirassiers in plumed helmets became a scene of strife between the ascending and descending throngs. This same scene of strife was more exaggerated at the narrow doorway where the in and out going masses met in full collision like the rush lines of football teams. Finally, the in team obtained advantage and pushed its way along so completely that fully a half hour elapsed before those without could gain entrance.

Many of the presidents of sections gave dinners or receptions to their members. These were delightful, as here men doing the same work met in social intercourse, learning to know the human as well as the scientific side of their colleagues or correspondents.

One of the most enjoyable of the small entertainments at which I was a guest was a luncheon at the house of Professor Lannelongue. Few people were present, and besides Madame Lannelongue only one lady, Mademoiselle Virchow, who with her father was staying with the Lannelongues. Both host and hostess were very warm hearted and genial, and the evident affection and dependency existing between Virchow and his daughter was delightful to observe. Both spoke English fluently, putting me at least at my ease. I scarcely ever hoped to meet on such friendly and intimate terms the great German professor, and I assure you I appreciated the opportunity. Although within a month of eighty years old, he was as bright,

active and interested as a youth, seemed not to know fatigue, and was as direct and forceful in his conversation, and as kind and thoughtful of the younger members present, as is possible to conceive.

In passing I must not forget to remind you that the great feature of entertainment was provided by the Exposition. Time does not permit me to speak of this, though it holds its place in any reminiscences of the congress — an exposition, a credit to the nineteenth century and to France, the like of which has never been seen nor is likely soon again to be repeated.

For the national delegates the dinner given at the Elysée Palace by the President and Madame Loubet was very enjoyable. I wish time permitted me to give you some idea of the sumptuousness and regality of a French presidential dinner. Though the State be republican, surely her ruler is surrounded by all any prince of the blood could desire. But most interesting of all, perhaps, was the President's garden party, at which not only were our members invited, but also members of other congresses then in session in Paris — the press, the students, etc. Fully 10,000 people were entertained, the Shah of Persia included. Representations of dances at various eras were given by a *corps de ballet* from the Opera, and a most delightful and interesting presentation they gave. The stage erected for the occasion under the gigantic oaks of the garden was unusually picturesque, while particularly pretty was the minuet of Louis the Fourteenth.

Of the visiting Americans who are they who enjoyed the most, and in general got the most out of this congress? Surely, I shall say without hesitation, those who understand spoken German and French — not one of such whom I met but was pleased with everything, thankful that he had come, and regretful when it was over. Does it not seem shameful that in these days of ours, when science has become so completely cosmopolitan, especially medical science, and we are so interdependent one nation of workers upon another, that any single individual should be turned out of college with degree of Bachelor of Arts or of Sciences without complete speaking as well as reading knowledge of the three great languages of the time — English, French, and German? In this respect foreign universities, particularly Russian and German, are still far ahead of ours, and to our mortification be it said.

And now you will ask, what was accomplished by this great gathering? It is hard to put one's finger upon any one thing especially. Perhaps no absolutely new discovery was promulgated, perhaps no great knowledge was individually acquired, but the inspiration each one of us received in seeing, hearing, knowing, and being associated with our fellow physicians the world over, many of whose names will live forever in the history of medicine, was profound, and can but serve to stimulate us to a loftier desire to accomplish something useful in our chosen field, and to a further satisfaction in belonging to that noble army of workers whose only desired reward is that they may live to further the ends of civilization by relieving to some extent the ills of mankind.

It seems small and provincial to decry the usefulness of these International Medical Congresses, when the very leaders of our profession have not only commended them in words, but have lent their enthusiastic support by constant attendance and active participation in the proceedings. The great medical triumvirate of the second half of the nineteenth century have been among the most ardent and vigorous champions of these gatherings — Pasteur, Lister, Virchow. They were present at the first, have been seen at many another, and two of them, at least, were still able to gallantly receive the homage of their fellows at this last meeting. The twentieth century now opens before us. Happy, indeed, if it produces three such men!

THE RADICAL TREATMENT OF LACHRYMAL DISEASES.[1]

BY WALTER B. LANCASTER, M.D., BOSTON.

THE great majority of cases of epiphora are amenable to the usual conservative treatment which consists of astringent and antiseptic collyria, syringing and probing, and occasional treatment of the nasal cavities. In spite of a judicious selection and skilful application of these methods there remain a considerable number of cases which are not relieved. To this class must be added those cases which might probably be cured, but cannot afford the time and expense of two to twelve months' treatment. A third class comprises those cases on which an operation is necessary, for example, for the extraction of cataract, which would not be safe so long as there is a focus of infection like the lachrymal sac communicating with the conjunctival sac.

In these three groups are comprised the cases for which something more radical must be done, since the prevalent methods are either frank failures or impracticable of application. I repeat that these cases are not rare and unusual, and that the disease is not only very annoying but a constant menace, threatening to cause ulceration of the cornea as the result of some slight abrasion which becomes infected from the discharge, or to cause phlegmonous inflammation as the result of infection of the tissue about the lachrymal sac. Any method of treatment which promises a quick and sure relief from such a condition is certainly worthy of attention.

Such a method, it is claimed, is to be found in extirpation of the lachrymal sac and gland, one or both as may be indicated. The surprising thing is that the operation has not become more common. Described as long ago as 1748, and, indeed, practised by the ancients, it has been practised or suggested by different writers with increasing frequency during the last fifty years, but has never become the fashion in this country. In 1881 40 cases of extirpation of the sac, operated on by Graefe, were reported; in 1889, 25 cases of extirpation of the gland by De Wecker. Since then an average of one to three reports have appeared every year on either sac or gland, nearly all favorable, almost all by European writers. Lawford is the only English, and Holmes, of Cincinnati, the chief American writer whom I have seen. In this vicinity the removal of the lachrymal sac by caustics or dissection, or both, has been practised at long intervals, the removal of the sac and gland apparently not at all. Hence I was inclined to assume that so obvious a method of treatment must have some decided drawbacks, or it would have gained greater vogue. The prejudice against it appears to have been either theoretical, based on insufficient knowledge of physiology,

[1] Read before the Boston Society for Medical Improvement, December 10, 1900.

which led men to say, "Remove the sac and close the duct and what becomes of the tears? Of course they run over! Remove the gland and what becomes of the cornea? Of course it dries up!" Or the objection has been that the operation was difficult, as most of the writers on the subject state. For example, Holmes says: "I do not consider the extirpation of the lachrymal sac and gland an easy operation." Czermak advises having two extra assistants who shall have nothing to do but hand sponges to the first assistant, and in general implies that the operation is somewhat formidable. Others take a similar view. A third possible explanation may be that the operation was not new, so that when it has been suggested the reply has been, "Oh, that has been tried before and given up." If it had been really new probably plenty would have been found to rush to try it, and of course report favorably.

With the sentiment rather strongly against the operation I waited for a fairly desperate case before venturing to try it. Such a case was encountered in a woman with an absolutely impermeable nasal duct and a lachrymal sac distended to the size of a small lemon by the long duration of the disease. It was filled with mucopus, which was infected with ozena, and which could be expressed in enormous quantities into the conjunctival sac at any time. Appearance and odor were disgusting, and the patient was anxious for any operation to gain quick relief. She lived in the Provinces, and could not waste time over treatment. The result of dissecting out the sac was so entirely satisfactory, and the patient was so grateful, that I tried it on other cases, and have been more and more favorably impressed as cases presenting possibilities of various complications have resulted favorably.

Given a case on which a radical operation is needed, which shall we advise? Removal of sac or gland or both? Removal of the sac takes away the source of irritation, and not only does away with the disease of the sac and its dangers, but diminishes materially the flow of tears; for the secretion of tears is a reflex affair increased by any irritation of conjunctiva as well as by other causes, for example, by irritation of the nose or retina and by emotion. The overflow of the contents of the lachrymal sac into the eye keeps up a chronic conjunctivitis which excites an excess in the supply of tears. Experiments on guinea pigs indicate that the extirpation of the *normal* sac is followed by a diminution, not only of the activity, but also of the size of the lachrymal gland, apparently by a compensatory atrophy. Be that as it may, there is no doubt that removal of the *diseased* lachrymal sac is followed by diminished flow of tears, especially after any conjunctivitis which may have existed is cured. If the patient is exposed to irritation, however, as in cold, windy weather out of doors, there is a considerable surplus which fills the conjunctival sac and causes annoyance. Nevertheless, since the condition is so much improved, the majority of patients are well pleased. But if either the surgeon or the patient is critical he deems the result a partial success only, in many cases. For this reason the second step was suggested of removing the lachrymal gland.

The moisture of the conjunctival sac comes from the mucous membrane of the conjunctiva from the group of small glands called accessory, or palpebral, or inferior, and from the much larger primary or superior lachrymal gland. The accessory or smaller glands may be reached through the conjunctiva, and many have limited their operation to the removal of these. The result is uncertain because the main effect depends, not on the removal of the accessory glands, themselves, which would be slight if it were possible to remove them alone, but on the damage done to the ducts of the large gland, which are numerous and pass through or among the smaller glands. Even the removal of the larger gland causes surprisingly little diminution in the apparent moisture of the conjunctival sac. It is only when the eye is exposed to stimulus that the difference is usually apparent, and then the diminution is relative. There is never an absolute dryness by any means. Our aim, I take it, should be to produce a condition where under ordinary stimulus no excess of moisture is present, and where, under any greater stimulus which the patient from his occupation is likely to encounter often, there is such slight overfilling of the eye as to require only occasional wiping. Since the diminution required is a relative one, there must be a difference of opinion between different operators as to how great a diminution each will call satisfactory. My experience has not been sufficient to make me dogmatic on this point. My present inclination is toward removing both sac and gland, and not only the large gland, but the greater part of the accessory as well.

There are some cases where removal of the gland without the removal of the sac seems to promise relief, and if so, is to be preferred. I mean those cases in which there is no obstruction to the lachrymal passage either to a probe of fair size or to water from a syringe, and yet the epiphora is great. Whether removal of the lachrymal glands would remedy this I cannot say from experience, for the only cases in which I have suggested it have not so far been operated. Favorable results are reported by De Wecker and others.

What are the dangers or disadvantages of the radical treatment? These may be divided into direct and indirect. Under direct results we must include the possibility of not obtaining primary healing of the wound, which might entail prolonged treatment with more or less disfiguring scar. Disfigurement might result from faulty technique. Should infection extend to the orbit the consequences of orbital abscess must be faced. If orbital hemorrhage of sufficient extent to cause blindness by injuring the optic nerve has followed strabismus operations, such a result might conceivably occur after extirpation of the lachrymal gland. The possibility of causing ptosis by damaging the levator in extirpating the gland has been suggested. As far as I know, none of these possibilities has been realized with the exception of the first. Some operators have failed to get primary union. In case this occurs after operating on the sac, and part of the mucous membrane has been left behind, the epithelium proliferates and an irregular suppurating cavity is formed which leaves the patient in nearly the same condition as before. Ectropion is reported as a result of faulty methods.

As an indirect result of an unfavorable character there is the possibility of excessive dryness after removal of the lachrymal glands. This is conceivable perhaps, but has never occurred as far as I have been able to learn.[2] There is also the possibility of injur-

[2] Holmes has reported 2 cases of temporal dryness which passed off in a few days.

ing the cornea during the operation by lack of care. It has been advised to protect the eye by a strip of plaster to keep the lids closed during the operation. In case an eye deprived of its main supply of irrigating fluid became infected, for example, in case of purulent conjunctivitis or keratitis, it seems likely that the lack of irrigation would put the eye at a decided disadvantage and necessitate most frequent artificial irrigation to take the place of the natural. On the other hand the removal of the sac which is a focus of infection renders such a keratitis or conjunctivitis less likely to occur. All these complications, including suppuration of the wound, are on the whole rather remote possibilities when proper technique is observed.

I know of but one instance of serious complication following the operation of removal of the lachrymal sac and gland. That was reported last spring by Veasey, and it seems clear that the keratitis which occurred was of an unusual type, and not to be regarded as a direct result of the operation *per se*. There was recovery with normal vision.

Since my object is to call attention to a method of treatment much neglected in this vicinity, I shall say nothing about the technique of the operation, but show some cases on which I have operated.

CASE I. This gentleman is a private patient, but was so well pleased with the result of the removal of his lachrymal sac that he is willing to be shown. He was probed more or less for six years, and had several lachrymal abscesses, with pretty constant epiphora between times. In removing the sac I excised the scars of the old abscesses and now, as you see, the cicatrix is practically invisible. He has some epiphora when the eye is exposed to irritation, for the gland was not removed. He is planning to have that done later. I advised waiting longer to see if removal of the sac alone would suffice.

CASE II. Removal of both sac and gland. This woman had epiphora with mucopurulent, bad-smelling discharge four years. She had abscesses every spring and fall. Her condition interfered seriously with her occupation as a domestic servant. The eye was "always running over." Now she states that once or twice a day it needs wiping, "sometimes it doesn't run at all." This case was operated less than two months ago, so that the scars have not yet disappeared. The first case has been done eight months. Both were out in five days.

These 2 are fair samples of the result in the other cases I have done, with one exception, which I will show after showing 3 recent cases to illustrate the immediate result — the amount of reaction — following the operation.

CASE III. This man has been treated in Paris and in Philadelphia by the usual methods. Result, O. S., impermeable stricture. O. D., probe $1\frac{1}{2}$ millimetres in diameter passes with little difficulty; sacs not enlarged, epiphora O. U. Sac and gland were removed on left side. Removal of gland alone advised on right side. It is only three and one-half weeks since the operation, and there are still plain traces of the ecchymosis and swelling and by palpation the induration about the buried skin sutures can be felt. The temporary ptosis which follows the operation as a result of swelling of the lid has not yet entirely disappeared. This patient was discharged on the fifth day, to come later on for operation on right eye.

CASE IV. This colored man has had long and serious trouble with his lachrymal drainage, his frontal and other accessory sinuses. He broke his nose thirty years ago at the age of six. When eleven years old he had an extensive lachrymal abscess, O. S., followed by prolonged suppuration, probably from caries. He found one day that he could blow out into his eye when he blew his nose. He says the doctors had failed to stop the discharge, but by practising this blowing he soon healed it up himself. It stopped discharging into the conjunctival sac, but the discharge into the nose still exists on both sides, though it has been much relieved recently by removing the anterior end of the middle turbinate, securing better drainage. As you see, his eyes are very wide apart, nearly 50% more than the average. This is the result of the tremendous thickening of the base of the nose from the formation of new bone which has gone on for so many years. When the lachrymal sac was removed the nasal duct was found to pass, not behind the lower inner margin of the orbit, but to enter the bone an inch below the margin of the orbit on the anterior surface of the superior maxilla. The whole sac was subcutaneous.

This case was operated on only ten days ago, and you can see that, as is usually the case, the chief reaction from the operation is an ecchymosis of skin and conjunctiva, and a slight swelling of the loose areolar tissue of the upper lid which causes a temporary ptosis of variable amount. You can feel the buried skin sutures.

CASE V. The last case I have to show is the least successful one I have done. This girl was treated by probing steadily for over a year. She dreaded it and it wore on her health. She fainted on more than one occasion when the eye was probed; once she was unconscious for over an hour, she says. Both small and large probes were tried.

The sac was removed with difficulty. It was the second case I had done and I did not do it as neatly as I ought. The scar is less conspicuous than the scars of her lachrymal abscesses which were excised, but there is a slight tendency to cicatricial ectropion, though not enough to expose the conjunctiva. If you look carefully you will see that the lower lid at its inner third does not rest against the eyeball as closely as it should. This makes an opportunity for mucus to collect. There is considerable chronic conjunctivitis which supplies the mucus. If the conjunctivitis were faithfully treated this condition would be relieved. The cause of the sagging of the lid is probably damage done to the orbicularis at the time of the operation plus slight cicatricial contraction. Six months ago this could be easily seen and therefore the case was not classed as a success. It is steadily diminishing and today is hardly noticeable. The patient and her family regard it as a success. Being relieved from her previous condition she has neglected to treat the conjunctivitis. I have shown it that your impression may be a fair one, not founded on selected cases.

I wish to emphasize one more point. You will find if you interrogate these 5 patients (and the same is true of all the others I have operated on, some half dozen in number) that as far as they themselves are concerned they are sure that they are better. The evident sincerity and the emphasis with which they state this, and stick to it in spite of cross-ques-

tioning, constitute an unanswerable argument in favor of the operation.

AN OPERATION FOR CATARACT.[1]

BY EDWARD L. PARKS, M.D., BOSTON.

ON the 14th of December, 1892, an Italian woman, thirty-five years old, was brought to my office by her brother. As she was nearly blind, she was led to a chair by my table. When asked if she could see me sitting before her, she replied that she could see only an indistinct form. I handed her my watch and asked her to tell me the time. With her right eye turned inward, the watch held closely to it on the other side of her nose, after a few minutes' study, she told me the time correctly.

A careful examination of both eyes was made. The right eye was undeveloped. In the left eye perception and projection of light were good. I diagnosticated in the left eye a capsulocretaceous cataract. With Leiter's electric light I was unable to penetrate it or to discover how large a proportion was capsular and how large cretaceous.

I talked to her substantially as follows: "It is a pity that a woman of your age should be blind. I will have nothing whatever to do with your right eye. I can do an operation on your left eye which will let in light, but I cannot promise that you will see. I will operate if you will give me authority to stop at any time and abandon the case, or to go on, as I choose."

Some days later her brother reported that she had liked the way I talked, and would like to have me operate immediately after Christmas. While thinking about the case, I received a specimen copy of a medical journal from Nashville, the leading article of which was by Landolt, of Paris, in whom I have the greatest confidence. His article was a discussion of the proper time to operate; but one of his conclusions was that you may operate at any time, provided you make a sufficiently large cut to remove the cataract. I determined to make a sufficiently large cut. At the same time I read the valuable contribution to "The American System of Surgery," by Thomson, of Philadelphia, and from it decided that the old-fashioned flap operation was best suited to this case.

At her home in Cambridge, assisted by her brother, who was not a medical man, I operated. She was laid upon an ironing board which rested upon two tables. I made a very large flap (*Lappenschnitt* of the Germans) and a large iridectomy. The anterior chamber immediately filled with blood, and, having told her that it would disappear in about a week, I left her.

The wound healed very quickly, but it was fully a month before the blood was absorbed. Thirty-seven days after the first operation, I did the second. Another large cut was made near the margin of the corner inwards. Fluid vitreous escaped. The cataract was found to be more capsular than cretaceous. The capsule was tense, like a tightly stretched drumhead, and it parted readily, as if by magic, at the touch of the cystotome, leaving a clear, round pupil.

Forty-four hours after the operation the eye was opened and seen with dim light. The seventh day eye quiet. The eighth day cut perfectly healed. The seventeenth day saw well. To make a long story short, there was a steady improvement in the sight from this time onward.

The first operation was done December 26th, the second the 1st of February. April 8th, vision was $\frac{1}{10}$. May 6th, ordered plus 10 D. for near work. June 29th, with plus $5\frac{1}{2}$ D., vision equalled $\frac{2}{10}$.

In the summer of 1899 I met her in a bicycle suit. I asked her if she rode the bicycle. She said that she did, with her husband or her brother to accompany her. As she had ridden through Boylston Street in the afternoon, when most of the heavy teaming is done, she must have felt pretty confident.

February 14, 1900. Now without glass reads the newspapers. Vision $\frac{2}{10}$. She prefers 4 to $5\frac{1}{2}$ D. for distance.

She said that she "had consulted all the great specialists in Europe, and they all said that she would become totally blind and advised her to let it alone." At the time I saw her, her relatives in Italy were writing to her not to let any doctor touch her eyes.

REMARKS UPON SPINAL COCAINIZATION SUGGESTED BY CASES SEEN AT TUFFIER'S CLINIC IN PARIS, AUGUST, 1900.

BY MAURICE H. RICHARDSON, M.D., BOSTON.

AT M. Tuffier's clinic at 10 A.M., one day in August, 1900, fifteen or twenty representative surgeons were present, among whom were Warren, Weir, Dennis, Murphy, Cushing, Mayo, Ochsner, Laplace and other Americans. The first patient was a woman of middle age, with a large abdominal tumor. She was seated upon the operating table, bending forward. The skin over the lumbar region was sterilized by scrubbing with soap and water, and later with an antiseptic, the nature of which I do not remember. A small, hollow needle about 3 inches in length was next inserted carefully into the spinal canal through a space to the right of the lumbar spine. The needle was slowly thrust in until thin fluid, slightly tinged with blood, escaped. The syringe, a small one, was then attached to the needle and the solution of cocaine was slowly introduced under gentle pressure. The place of introducing the needle, the amount and strength of the solution, are immaterial. I do not recall exactly these points, which, for purposes of this communication, are, as I say, unessential. The immediate effect of the procedure was not noticeable. There was no outcry and no visible effect upon the patient. She was at once placed recumbent and her abdomen sterilized. In the meantime M. Tuffier prepared himself. At the end of about ten minutes — perhaps less — with the patient in the horizontal position, two large ovarian cysts were removed, and the incision closed. At this time I had an opportunity of examining the pulse. It was barely perceptible; its rate was between

60 and 70. The face was pale, the expression anxious. During the whole operation there was no outcry, no struggling, no restlessness. In answer to repeated questions there was the invariable reply that there was no pain whatever. The operation lasted about twenty minutes and was skilfully performed. As a demonstration of complete anesthesia it was a brilliant success. As a whole, the operation and the operator impressed me — and I think, all present — most favorably. Nothing could be more satisfactory than this demonstration of the efficacy of the method of anesthesia.

The second patient was a woman of from thirty to thirty-five with a tumor of the left kidney. Cocaine was injected as in the previous case, with the same success. The patient said that she felt paralyzed. The operation was much more difficult than the other, but was brilliantly accomplished. The patient repeatedly answered that she felt no pain. She was, as I remember it, nauseated at or before the close of the operation. This was said to be a not unusual occurrence. The pulse was extremely feeble, but not accelerated. The face was pale, the expression anxious. M. Tuffier said that it was not unusual for the temperature to rise several degrees after the operation, but that it quickly subsided.

The impression made upon me at the time was great. The method of administration was quick and sure. The spinal canal was at once entered without greater suffering than would naturally be caused by the deep insertion of a small needle. There was no hemorrhage, or not more than enough to redden slightly the cerebrospinal fluid. The rapidity and efficiency of the anesthesia were remarkable. The great abdominal operations were admirably borne; and yet the whole impression was distinctly unfavorable to this method of anesthesia. The patients appeared in actual danger. The facial expression, the pallor, the pulse, were not unlike those of a patient in deep shock. Such an appearance I have seen, and would perhaps expect after the removal of a renal tumor filling the left side of the abdomen, however mild and successful the anesthetic. I should not expect it after the removal of uncomplicated ovarian cysts under ether anesthesia. The condition would indicate the hypodermic or the intravenous infusion of normal salt solution, or at least of brisk stimulation and artificial heat.

On the other hand, the appearance of these patients I have seen in simple faintness, not resulting necessarily from pain, but from mental shock, or even from the sight of blood. The pulse and expression may have been owing simply to the realization and horror of what was going on.

The advantages of spinal over general anesthesia, however great it may be under certain circumstances, cannot be demonstrated except by years of observation and by thousands of experiments. I do not feel at all convinced that this method is without serious dangers. Time alone will show what and how great these dangers are. There are, it seems to me, definite indications for the adoption of the method — indications which will permit its adoption by even the most conservative. This limited field may, if increased knowledge proves safety, gradually become widened.

From the anatomical point of view, however, it is inconceivable that the introduction of the needle into the spinal canal can be without danger, especially if the method is practised by every one. I recall the great plexuses of veins which surround the vertebræ and the dura mater of the cord, as I have demonstrated them many times by solidifying injections. The cauda equina, too, cannot but be liable to puncture or other injury by the introduction of the needle. Indeed, one of the Americans present told me that a patient of his suffered for several months from paralysis of the bladder after this method of anesthesia.

The extent and gravity of the danger can be known only by repeated use. Judging from the occasional effects upon the heart produced by subcutaneous injections of cocaine, there must be some danger at least of cardiac depression when the solution is intradural. The dangers from the subcutaneous use of cocaine are apparently slight, however. I have seen but 1 case in which there was cause for the least anxiety. The patient received a urethral injection of 4% solution of cocaine preparatory to the introduction of a sound. He became suddenly collapsed; the pulse was feeble, the face pale, the respiration sighing. His general appearance was not unlike that of M. Tuffier's patient. Under stimulation the disagreeable symptoms disappeared.

Finally, there is the danger of introducing sepsis into the spinal canal through the needle. In skilled hands this danger is so slight, however, that I should not object to spinal cocainization on such grounds. The chief objection, after all, lies in the fact that a drug, the dangers of which are not fully known, is introduced into the spinal canal, whence it cannot possibly be removed, and where it must be left to work out its peculiar effects, however beneficial or however injurious these effects may be.

A feature of general anesthesia which is too little appreciated — which is, indeed, often forgotten, but which is one of its chief advantages — is that blessed oblivion which envelops the patient from the beginning to the end of the operation. He loses consciousness in his own bed; he wakes there; he escapes all those horrors of the operation which the imagination can depict and fear inspire.

Clinical Department.

THE PURULENT RHINITIS OF CHILDREN AS A SOURCE OF INFECTION IN CERVICAL ADENITIS.[1]

BY CAROLUS M. COBB, M.D., BOSTON, MASS.

MARY E. B., age five years; was brought to my clinic at the Lynn Hospital July 13, 1900, with enlarged glands on both sides of the neck, just below the angle of the jaw. The mother said that she had noticed the enlargement for about ten days and immediately following an acute coryza. The family history was good, none of the near relatives having had tuberculosis in any form. The throat was free from inflammation, and the tonsils were not enlarged or diseased, but the mucous membrane of the nasal chambers was covered with a dried mucopurulent secretion.

The history of the case is as follows: The child was free from disease of the upper respiratory tract

[1] Read before the Essex South Branch of the Massachusetts Medical Society, December 21, 1900.

for the first two years of her life. At the age of two years she had diphtheria, and, as the mother expressed it, she had had trouble with her throat and nose ever since. I saw the child when she was four, and she then had enlarged tonsils, adenoids and the purulent rhinitis of children. I removed the tonsils and adenoids. The operation was done under ether and was thorough. Following the operation the breathing was very much relieved, but the purulent discharge from the nose did not entirely cease, although it was much less.

To sum up the history of the case, a child without any history of previous trouble with the nose or throat has diphtheria at the age of two years, and has a purulent discharge from the nose following this attack; two years later enlarged tonsils and adenoids are removed, and one year after the operation she still has a purulent discharge from the nose and a cervical adenitis following an acute coryza.

I have selected this case because it is typical of a class of cases which the general practitioner sees every week of his professional life. We are all familiar with the open-mouthed, pale, partially deaf, inattentive and mentally backward child, with half-opened eyes and an undeveloped face, and thanks to Wilhelm Meyer these children are no longer allowed to reach adult life handicapped by the effects of adenoid vegetations. That these growths may be the result of an infective disease in the nose or throat there can be no doubt, and it is equally true that the obstruction which they cause may tend to prolong a catarrhal condition in the nose. It is very probable that adenoid vegetations may be the source of infection in many cases of cervical adenitis, but it is not our purpose to discuss adenoid vegetations. That ground has been thoroughly worked out in the past, but in spite of the number of papers which have been written and the opinions which have been expressed, I still believe that there is something new to be said about the origin and effects of adenoids. Of late the tonsils have been thoroughly investigated as portals of infection through which cervical adenitis might originate, and the fact has been firmly established that many cases do originate in this way, but compared to the whole number of cases those caused by tonsillar infection are only a small percentage. There can be no doubt but that every case of adenitis in the cervical region is as truly the result of infection as adenitis in any other part of the body. Every physician today looks for the source of infection in each case where he finds enlarged glands, that is, he assumes at once that the adenitis is a symptom and not the primary disease, and while the inflamed gland may require attention, he directs his chief efforts to the cure of the primary disease. This is the rational and truly scientific method adopted in dealing with adenitis in every part of the body except in the neck.

It would be interesting to know how many operations for the removal or evacuation of enlarged or broken down cervical glands are done each year in this State alone. These operations are done with hardly any attempt to find the source of infection. If the patient has enlarged tonsils or adenoids these are removed, but the effort ends there, and the subsequent treatment of the adenitis is in direct opposition to modern surgical teaching. The plan of treatment usually followed in dealing with cervical adenitis is the merest empiricism. The patient is given iron and cod-liver oil, because it is evident that he is suffering from sepsis, and various kinds of ointment are rubbed into the skin, and finally surgical intervention. Is it any wonder that these cases are protracted? But it may be contended that many of these cases recover with the treatment adopted or by the aid of surgery; this is undoubtedly true, but, on the other hand, it is equally true that many of them run a protracted course even after surgical intervention, and it may well be questioned whether the final healing of the adenitis is due to the treatment directed to the glands or to the spontaneous healing of the source of infection. I do not wish to say anything that can in any way be construed as speaking against operations on these glands, because these operations are often necessary, not only for the health of the patient but for cosmetic purposes as well, but I do wish to enter an earnest plea for the treatment of these cases on the same lines that govern the treatment of adenitis in other parts of the body. The operation will, if thoroughly done, relieve the patient from the danger arising from the glands already involved, but it will not prevent the involvement of other glands unless the source of infection is found and healed. The source of infection which causes cervical adenitis is very probably in close proximity to the glands involved, that is, the mouth, throat, nose or ear. There is, however, a small percentage of cases which are caused by general systemic infection, although this percentage is not so large as is generally supposed.

When we come to consider the sources of infection in cervical adenitis, we are met with the generally accepted belief that these cases are practically all due to tubercular infection, and the meaningless statement that the child is strumous or scrofulous. The words struma and scrofula have come to occupy the same place in our conversation with the friends of the patient that was formerly occupied by "congestion of the portal circulation," which the late Oliver Wendell Holmes wished had not passed out of use, because "they sounded so well, meant so little, and were so satisfying to the patient," and while these words may still have a limited use for this purpose, it will be as well for accuracy of statement in medicine when they pass out of use altogether. If we mean tubercular infection, why not say so, and if we mean something else, why not say that as well? There is no evidence that any considerable proportion of these cases of cervical adenitis is due to tubercular infection. If they are due to tubercular infection, it must occur in one of two ways, either as a general systemic infection or as a local infection from the parts immediately surrounding the neck. If due to systemic infection it would naturally follow that we should find manifestations of the disease in other parts of the body, and if due to local infection we should find the original lesion, or the scar tissue, the result of the original lesion, at the point of entrance of the infection. From the well-known tenacity with which tubercle bacilli persist in the tissues which they have once invaded, we might reasonably expect to find diseased tissue at the point of entrance, and this is what is actually found in many cases of diseased tonsils.

I do not intend at this time to discuss the whole subject of cervical adenitis, but I do wish, in this connection, to call your attention to the purulent or muco-

purulent diseases of the nasal cavities as a possible source of infection. Perhaps this can be done in no better way than to analyze the course and symptoms of the case which I have given. The child was free from catarrhal disease of the upper respiratory tract for the first two years of her life; at least the mother, a very intelligent woman, says that she never noticed any trouble of that kind; then she had diphtheria, and has had so-called catarrhal disease of the nose and throat ever since. I saw her when she was four years old and she then had enlarged tonsils, adenoids and purulent rhinitis of children. I cleared the throat and the breathing was much relieved, but the purulent rhinitis continued, although it was much less. One year later she returns with an acute cervical adenitis following an acute coryza. In this case we have a purulent rhinitis as a direct sequel of the attack of diphtheria, and we have therefore two questions for solution: (1) What is the source of the purulent discharge from the nose, and (2) what causal relation, if any, does the attack of diphtheria bear to this discharge? In answer to the first question it may be well to make the statement that a chronic nasal discharge, with a few exceptions which I will give later, always has its source in the nasal accessory sinuses. The exceptions to this statement are the cases of foreign bodies or of dead bone, which is essentially a foreign body, in the nose, and syphilitic and tubercular disease. The foreign bodies produce a profuse, purulent discharge, while the syphilitic and tubercular diseases produce a slight amount of discharge *per se*. I am well aware that syphilis is credited with causing a nasal discharge in a large number of cases, but if we take the trouble to differentiate the discharge caused by the actual syphilitic disease from that caused by the results of this disease within the nasal chambers, we shall be in a much better position to treat these patients intelligently. These results act as a predisposing cause of a nasal discharge in precisely the same way as obstruction to drainage from the cells produced by other causes acts, or a sequestrum may be left after a destructive syphilitic inflammation of the bone, which acts simply as a foreign body. It acquires no specific qualities on account of its origin and its complete removal has the same influence over the discharge that the removal of any foreign body has.

I will not go fully into a consideration of the predisposing and exciting causes of sinus disease as I have done it elsewhere very lately.[2] What causal relation does diphtheria bear to this discharge? The relation of diphtheria of the throat or nose to sinus disease presents itself in one of two ways; either there may be a true diphtheritic membrane formed in the accessory sinuses, especially in the antrum of Highmore during the attack of diphtheria (Weichselbaum, E. Frankel, Dmochowsky), or the sinuses may be intensely inflamed during the course of the diphtheria without true diphtheritic infection, the inflammation being due to a secondary infection by other bacteria (Zuckerkandl). Here, then is the relation of the diphtheritic attack to the subsequent purulent discharge. In this case the attack of diphtheria was the exciting cause, but in other cases it may be acute coryza, influenza, croupous pneumonia, scarlet fever, measles, facial erysipelas, typhoid fever, cerebrospinal meningitis, foreign bodies in the nose, etc., in fact, any way in which infection may reach the sinuses. Infection having taken place and the discharge once established, absorption will sooner or later occur, and the lymphatics of the nose being directly connected with those of the neck, a cervical adenitis may result at any time, and unless the purulent rhinitis is cured the cervical adenitis will run a protracted course. The purulent discharge from the nose may not cause a cervical adenitis for some time, because the retained secretion is very largely contained in bony cavities, but it eventually denudes the mucous membrane over which it flows and then some condition, as an acute cold, blocks the flow of the purulent discharge and absorption of the retained secretion takes place. If the source of the infection is in the nose, as it evidently was in this case, as there was no inflammation of the throat and no tonsils to be seen, and no pockets around the throat to retain the products of inflammation and no evidence of tuberculosis, then the importance of treating the nasal disease does not need to be insisted upon. It seems hardly necessary to add that so long as the source of infection remains unhealed that it is hardly reasonable to hope to cure the adenitis. It is very true that the infected glands can be removed and the process stopped in them, but this does not prevent others from becoming involved, and one would hardly care to remove the whole lymphatic system of the neck to prevent recurrence. It seems more in the line of modern surgical teaching to first find the source of infection, and to make the healing of this the objective point of the treatment. If this can be done, the treatment of cervical adenitis will be much easier, and its course much shortened, and while the removal of hopelessly involved or broken down glands will still be necessary, we shall be able to prevent the involvement of other glands.

Medical Progress.

REPORT ON PROGRESS IN OBSTETRICS.

BY FRANK A. HIGGINS, M.D., BOSTON.

(Concluded from Vol. CXLIII, No. 25, p. 635.)

THE DOCTOR'S DUTIES TO PREGNANT WOMEN BEFORE LABOR.

DR. AYERS[4] says women should be instructed to engage their doctors as soon as they consider themselves pregnant. Such patients should then be instructed, first, in the cardinal rules of gestation; frequent but never prolonged outdoor exercise and brief rests in the recumbent position, with low-heeled shoes and shoulder-strap support to the skirts, corsets being laid aside; a sensible diet that avoids an excess of meats; regulation of the bowels and steadiness in the perspiratory function. The chief cause of unintentional abortion in healthy pregnants is prolonged or overexertion on the feet, constipation, and perhaps coition. The nausea of pregnancy, so usual in primiparæ, aids in many cases by its restraining influence the conservation of gestation. Young wives are prone to play bravado during the unshowable first months of pregnancy, and to try to do all they did previous to impregnation. Urinary examinations should be made once a month from the third to the seventh

[4] International Medical Magazine, January, 1900.

month and every two weeks from then to the ninth month, then every week until labor. The most practical method for obtaining a warning of the need of a urinary examination is to instruct the patient to give immediate information of any reduction in the amount of urine passed in twenty-four hours. Examinations should note the twenty-four-hour amount, the specific gravity, the reduction, if any, of urea and the presence of albumin and casts. Very few cases of eclampsia would occur if proper attention were given to the urine.

The question of ante-partum examinations is a broad one, but it involves 50% of the obstetrician's usefulness. If the patient is a primipara the pelvis should be measured by the twenty-eighth week. We should obtain the diameters of the iliac crests, anterior superior spines, the external and internal diagonal conjugata, and in misshapen pelves the external obliques, interischial and symphyseococcygeal diameters. Compare these diameters with the height and weight of the patient and her husband, their ages, and note the character of the mother's skeleton. A frame of light bones usually has a relatively large pelvic calibre, estimated from the external measurements, and vice versa.

In multiparæ where the previous children were of full size and term and the labors normal these measurements are not required, but a comparison between the size of the fetal head and that of the pelvic cavity should be made a fortnight before labor, since there may be an overgrowth of the fetus.

The principal facts to be ascertained by abdominal examination are the position of the fetus, twins, fetal vitality, grades of hydramnion, condition of the bladder, tumors in the abdominal cavity, and complications involving the kidneys, liver, heart, lungs, etc. Fetal malposition is frequent in proportion to the amount of amniotic fluid present. Malpositions present at the seventh month, where there is much room for fetal gyrations, do not necessarily persist, since usually with time the fetus daily represents a gain in space occupied compared with the amniotic fluid. But women with malpositions of the fetus should be examined every two weeks. External version may be final, if performed when the fetus is getting fixed in a malposition. Twins are usually a surprise, but need seldom be so, and often cause dangerous complications in delivery and the confusion incident to the arrival of the unexpected guest. Two heads, two heart rates and innumerable extremities are full of valuable diagnostic suggestions.

In habitual premature fetal death a weekly record of the fetal pulse should be made from the sixth month to labor. Patients with hydramnion should have the anemia usually accompanying it combated, and should be instructed when labor pains first occur to lie as still as possible in bed until amniotic rupture takes place, in order to avoid prolapsus funis or malpresentation of the fetus. Abdominal tumors may not be noticed by the patient, but should not escape the examiner's eye.

At least one vaginal examination should be made a few weeks before labor time, with an eye alert for placenta previa, exostoses, fibroids, ovarian tumors, atresia, pelvic contraction, cancer, vaginitis, etc.

The nipples should be examined a month before labor, milk scabs, abrasions and fissures treated, and depressed nipples elongated by traction daily.

PROGRESS IN OBSTETRICS DURING THE PAST TWENTY-FIVE YEARS.

Professor Fritsch [5] contributes an interesting paper on this topic for the anniversary number of the *Deustche medicinische Wochenschrift*, January 4, 1900. The gist of his summary is as follows: Our therapy of abortion has become more active, the degree of interference is greater. Our views of Cesarean section have undergone great changes, and the mortality of the operation has sunk from 50% to 5%. Naturally antisepsis is held partly responsible for this great advance. The discussion has become bitter over the relative merits of the Porro and conservative operation on the womb, with a relative victory for the latter. Perforation as a relative indication has now become almost a crime. Symphyseotomy has not yet won a permanent place for itself, despite the labors of its able champions. The technique is perfect, but the indications remain uncertain. The Walcher position, according to Fritsch, is a much more valuable contribution to modern midwifery. We have not much to boast of in connection with eclampsia. The most important advance here is Leyden's discovery of the "pregnancy kidney." Fritsch believes that narcotics have killed many an eclamptic who might otherwise have recovered. In pelvimetry we now have the instrument of Skutch for obtaining the true conjugate, and are no longer compelled to guess at it. Bandl's labors towards a better understanding of uterine rupture deserve recognition, as do the demonstrations of Fehling and Latzko that osteomalacia may be cured respectively by the operation of castration and the internal exhibition of phosphorated oil. The advances in the management of puerperal infections due to the application of the principles of antisepsis and asepsis are too well known and understood to require much space here. Absolute sterilization of hands we know to be neither attainable or necessary. Bacteriologists have not helped the practitioner much thus far. Ahlfeld has doubtless done good service to the practitioner in his antagonism of Credé's teachings in management of the third stage of labor, with regard to expectancy. Finally, the improvement in society and journalistic work in connection with obstetries is not the least advance along the line.

LABOR COMPLICATIONS AFTER FIXATION OF THE UTERUS.

Operations for fixation of the uterus have been so much in vogue during recent years that the results on subsequent pregnancies are now being observed and the dangers pointed out. In this connection Rühl [6] points out some of the serious complications of labor as the result of both vaginal and ventrofixation of the uterus. He says that the danger is greatest when the top of the fundus is fixed to the anterior vaginal wall in the vaginal operation, and in the abdominal operation when the fundus is fixed to the abdominal wall just above the symphysis. The obstruction to labor may be so serious that although the pelvis is of normal dimensions, Cesarean section may be required. He notes that Cesarean section when performed for this cause has been attended by the very high mortality of 50%. In a normal pregnancy at the fortieth week the long axis of the uterus lies exactly at right angles to the plane of the pelvic

[5] Obstetrics, February, 1900.
[6] Centrbl. f. Gyn., 1896, No. 51; 1900, No. 13.

inlet. After fixation the fundus is much lower than it should be, while the cervix is drawn up and retroposed, with the result that the uterine axis may be at an angle of only about 40° with the plane of the inlet. When uterine contractions occur under these conditions the tendency is for the presenting part to be driven backwards against the sacrum, instead of downwards and backwards in the pelvic axis. The cervix may be drawn so far up and back as to lie above the level of the sacral promontory, and the true pelvis may be bridged over by the anterior wall of the uterus and vagina in such a way as to leave between the anterior lip of the cervix and the sacrum no room for the passage of the child, or for the manipulations necessary for artificial delivery. In these cases the author advises an anterior uterovaginal section, consisting of an incision passing through the anterior lip of the cervix, the anterior uterine wall and vagina, after as much natural dilatation of the cervix as possible has been obtained.

Kallmonger[7] reports a case of Cesarean section after vaginal fixation in which at the seventh month there were symptoms of threatened miscarriage relieved by prolonged rest in bed, but at term labor began with the axis of the uterus running anteroposteriorly and the fetus lying transversely. After sixteen hours of labor no progress had been made and it was feared that the posterior wall of the uterus would rupture. Cesarean section was performed and in the operation the anterior wall of the uterus was not seen at all, while the posterior wall was as thin as paper. The woman did well, but the author recommends the early induction of premature labor.

A case of rupture of the uterus at the Munich Maternity after vaginal fixation is reported by Frickhanger.[8] In this case dilatation was normal, but the head could not be reached by forceps and version was performed, a contraction ring being encountered. The child survived, but the mother died on the fifth day of peritonitis, due to rupture of the vagina and posterior part of cervix. The reporter concluded that on account of the vaginal fixation the anterior lip of the cervix could take no share in the dilatation, so that there was an unusual strain on the posterior lip and neighboring part of the vagina.

DIMINUTION IN THE SIZE OF THE SHOULDERS IN DIFFICULT LABOR.

Bonnaire,[9] in the *Presse médicale*, March 14, 1900, describes 2 cases in which cleidotomy division of the clavicle was performed in order to extract the fetal body after the head had been broken up by the basiotribe. In one case double cleidotomy was necessary, in the other unilateral sufficed. From 5 experiments on dead fetuses he found that the double operation reduced the size about 10 centimetres. Cleidotomy has as yet been performed only on the infant already dead, and it is indicated when the shoulders cannot be extracted by ordinary or other means, as in pelvic contraction, when they become impacted in the cavity after the head has been broken up, when the shoulders are excessively broad and when it is necessary to reduce to a minimum the efforts at extraction, as in rupture of the uterus. It is performed with strong scissors or with a perforator. When the operation is impracticable through the folding forward of the shoulders or from other causes, Bonnaire recommends and has successfully practised another procedure called "supra-acromiotomy," or deep division of the soft parts over the anterior supra-acromial region. These operations are usually to be regarded as supplementary to cephalic embryotomy, but Bonnaire thinks that cleidotomy may be permitted even in the case of a living infant whose head has been born, but whose shoulders remain fixed, for in the experimental cases the subclavian artery has never been wounded nor the subclavian muscle cut.

PUERPERAL ECLAMPSIA TREATED BY DIURETIC INFUSIONS.

Dr. Jardine[10] reports a series of 22 cases of eclampsia treated by diuretic infusions. He says that in the actual seizures of eclampsia diuretics by the mouth are too slow in action, and that for the past three years he has been giving saline infusions consisting of sodium chloride and potassium bicarbonate or sodium acetate. The infusions are given usually under the breast. In his first 12 cases he used potassium bicarbonate and sodium chloride in equal parts, a drachm to the pint. In the last 10 cases he has substituted sodium acetate for the bicarbonate of potash, using 1 drachm of it with 1 drachm of sodium chloride to the pint of sterilized water at a temperature of 104°. One to 3 pints may be used at a time and is repeated if necessary. Aseptic precautions are rigidly followed, but the author has never had any sloughing or abscess formation in 200 infusions. He feels confident of the diuretic action of the infusion, as in some of his cases from 60 to over 100 ounces of urine were measured in the first twenty-four hours. In several cases analysis of the urine before and after infusion gave a marked increase in urea and uric acid after infusion. In addition he gives chloroform, veratrum viride, chloral and bromide, and magnesium sulphate. The obstetric treatment is varied according to the condition of the patient. If there is no indication of labor he does not empty the uterus unless the convulsions continue, and then if dilatation is difficult the cervix is freely incised. Cesarean section he thinks unjustifiable in these cases, as the results have been anything but good. Of the 22 cases treated by diuretic infusion, most of which were very severe, all but 5 recovered, and 1 of these 5 died on the seventh day of perforating duodenal ulcer. This case being properly omitted, leaves a mortality of only 4 in 22 cases, which is noteworthy in a series of hospital cases.

PLACENTAL TRANSMISSION.

Doreland[11] reviews the subject of placental transmission of drugs and specific diseases, and from the meagre literature derives these very suggestive, if not conclusive, arguments:

While many drugs may be administered to the mother without any noticeable effect upon the fetus, there are certain substances that show a special tendency to traverse the placenta, and entering the fetoplacental circulation, exert a positive influence for good or evil according to the condition that may be present in the given instance. Maternal medication, therefore, is indicated in certain conditions, either in

[11] The American Gynecological and Obstetrical Journal, June, 1900.

order to prevent the development of a similar condition in the fetus, or to counteract the effect of germs and their toxins already introduced into the fetal economy.

The drugs that have been found to effect the fetus in utero are notably opium, mercury, copper, lead, arsenic and the iodides. In appropriate doses they may be administered to the mothers in suitable pathologic conditions with beneficial results to both mother and child. Any morbific influence acting upon the mother either acutely, as in the case of the exanthemata, or more slowly, as in tuberculous and specific infection, will react deleteriously upon the product of conception and either destroy it through its overwhelming toxic action, or render it feeble and less resistant to subsequent and post-natal invasion, or the disease will run an atypical course in utero with or without apparent vestiges at birth.

The entrance into the fetal structures is accomplished through the agency of the fetoplacental circulation. It is probable that access is gained through bacterial action, the germs rendering the placental villi less resistant to invasion, whereby both the microbes and their toxins pass the natural barrier at the chorio-decidual junction.

As a rule the infectious diseases do not manifest their characteristic visceral lesions in the fetus, probably because of the passivity of these organs during antenatal existence. The germs, however, may be detected in large numbers by bacteriologic and microscopic examination.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

A. K. STONE, M.D., SECRETARY.

Regular meeting, Monday, December 10, 1900, Dr. E. H. Bradford in the chair.

Dr. W. B. Lancaster presented a short paper on

THE RADICAL TREATMENT OF LACHRYMAL DISEASES.[1]

Dr. C. H. Williams: I am very glad to have Dr. Lancaster bring this subject up because I think it is one which should have more attention. In many cases certainly the operation gives excellent results, better than in any other way. My brother Edward, who spent about a year at the clinic of Professor Völkers, tells me that the latter does the operation in many cases and thinks very highly of it. He generally removes only the sac and not the gland.

Dr. Standish: I have had very little experience with the operation. Ten or twelve years ago I performed this operation in 3 or 4 cases. In each case I was unfortunate enough to get infection, and I never operated by this method again. Probably the infection was due to faulty technique, but it discouraged me.

Dr. Jack: I can speak of 1 of these cases from personal knowledge — the young lady. I saw her for months. She went from my service to Dr. Lancaster's at the City Hospital. I tried all manner of things, and at the last tried to do the more radical operation of cutting the stricture all the way down, and then using Theobald probes of large size. This was kept up a while, I thought with a little improvement, but she was still very bad when I left her. One could not do anything more radical than this, outside of the operation which Dr. Lancaster has described.

Dr. Edward L. Parks read a paper entitled

AN OPERATION FOR CATARACT.[2]

Dr. H. Barton Jacobs, of Baltimore, Md., late secretary of the American National Committee, read

A SHORT ACCOUNT OF THE RECENT INTERNATIONAL MEDICAL CONGRESS AT PARIS.[3]

Dr. J. C. Warren: I am very happy to testify to the accuracy of the extremely interesting paper of Dr. Jacobs. The feature which interested me more than any other in the congress was the assemblage of men. It seemed to me that this was one of the most attractive features to the stranger who had not visited any of the congresses in Europe or in this country for a great many years; that it was an exceptional opportunity to see the men who had sprung up in the last generation, and the gathering in Paris at the end of the century certainly offered an opportunity which was not likely to occur again for a long time. And such proved to be the case. I can bear testimony to the statement of Dr. Jacobs that the men who visited the congress were men of the highest standing in medicine throughout the world. They all took an active interest in the proceedings and took part themselves. The leaders of the various countries were there, and it was a grand opportunity to be able to see these men, hear them speak and speak to them. I think the social side of these congresses is a very important feature, and I think it was so felt by the men themselves, by the Frenchmen particularly. I heard many allusions to this feature of the congress, that although they recognized that a great deal of excellent work was being carried out, none the less interesting were the social gatherings where men could be introduced to one another and exchange views about methods of treatment, operations or scientific questions, that they would not be able to do in the more formal gathering. Dr. Jacobs has alluded to most of the social features which I had the pleasure of attending. The receptions at the Elysée Palace which I attended were most interesting and dignified. The early morning reception was a particularly interesting one, as it included a small number of select men from each country gathered in a hollow square around the reception hall of the palace, the President going from one group to another making a few graceful greetings to the representatives of each nationality. The afternoon reception at the Elysée which came at the end of the congress was really a most artistic and picturesque affair. The gardens are very beautiful. The palace stands at the head of a lawn which slopes gently away and is surrounded with fine trees. At the end of this was a temporary theatre in which the most classic dances were given; not simple ballet, but a most artistic representation. No Roman festival could have been more classic and imposing in its conception and execution.

The opening of the congress in the Salle des Fêtes

[1] See page 34 of the Journal.

[2] See page 37 of the Journal.

[3] See page 29 of the Journal.

was also a very attractive feature of the congress. This is the largest room I was ever in, possibly excepting St. Peter's. It was a dome-shaped affair, perfect circle, and of a diameter which made an individual seem very small indeed, and, although I am not familiar with the exact dimensions, it would take an enormous assemblage to fill it. The congress, containing several thousand, did not fill more than half of the room itself.

This meeting was certainly an interesting one, as it gave us an opportunity to see representatives of all the nations of the world coming forward and extending their greetings to the congress. The reception in the Luxembourg Palace was hardly to be considered as a success. It did not seem to me the French could handle very large bodies as well as we were able to do it at our Columbian Exposition.

The part that interested me most was naturally the surgical part, and our party visited several of the hospitals. Doyen's was one of a number of places we went to. No one could but be impressed with his mechanical ingenuity and great operative skill. One would perhaps be more impressed with this feature than with other qualities which go to make a great surgeon. He has worked very hard to hold his own against the red tape which every aspirant for surgical honors in Paris must bow to if he wishes to reach the top of the ladder. He is working entirely independently. He is a great mechanical genius and there is hardly an instrument in his hand not designed by him. His rapidity of operating was great and his skill certainly was exceptional.

Tuffier impressed me very much indeed — a charming gentleman, evidently one of the leading surgeons of Paris. He is a beautiful operator, and he carried out his method of anesthesia with great ease and skill. The operations I saw were very important, one double ovariotomy, another removal of the kidney, done rapidly and without effort on his part, and entirely successful as far as anesthesia was concerned. Both the patients, however, seemed to be in a condition of marked shock shortly after the operation — faces blanched, respiration shallow and hurried, eyes rolled up and the pulse almost imperceptible. I could not feel the pulse at the wrist in one of the cases, and the patient complained of distress and nausea. Tuffier turned it off with the expression, "mal de mer," and paid no attention to it, and the nurse carried the patient out in that condition and he maintained that they all did well. A patient in that condition in one of our wards would receive a good deal more attention than was given to them on that occasion.

I think no American surgeon could help being struck with the lack of perfection in details of aseptic and antiseptic technique in surgery at most of the Paris hospitals. They certainly do not compare with what one sees in the best clinics in this country and one can say the same of Great Britain. There was a distinct disappointment to all the visiting Americans that they did not see better work at the hospitals they visited. I do not speak of the North German hospitals, because I did not visit them, but those I did see in the middle parts of Europe I certainly was not impressed with. They have little idea in some of the countries of aseptic surgery; no apparatus for sterilizing on a large scale as we see in our large hospitals. The hospitals in Paris are mostly old, and it is only here and there in certain portions of them an attempt has been made to bring them up to date and then in a way certainly not on a scale that would be at all satisfactory to an American surgeon.

DR. RICHARDSON: In reference to the clinic of M. Doyen I should like to say that I was very much impressed with it. I thought it as good surgery as I had ever seen. About his surgical judgment I know nothing. The first operation that he performed was opening the skull in a most effective way after it had once healed from a previous operation. We saw the beautiful first intention of his first incision. He thought that not quite enough bone had been taken out at the first operation and he therefore removed a little more. He showed us his electric saw, which worked to a charm. The hysterectomy and one or two other operations he did with great skill, and it seemed to me with great care, although he worked rapidly. He was rapid where a man may safely be rapid, and cautious where a man ought to be cautious. He was rapid until he got to the ureters, and then very careful, and once or twice, where he thought he might be in danger, he was slow and painstaking. The moving picture machine is a most vivid and an excellent way of teaching operative methods. One can get a perfect idea of every step of an operation. By means of this machine it would be possible to demonstrate the methods of every surgeon. If there were any step of the operation not understood, the machine could be stopped and any single photograph could be studied until it was fully understood.

DR. GEO. B. SHATTUCK: I was quite surprised to see my name on the programme as one who was to address the meeting this evening. I incline to explain its being put there on the supposition that I represent the considerable class who did not go to the congress. I was not there and I have no personal experiences or reminiscences to relate. I congratulate the meeting upon having had the pleasure and the profit of listening to Dr. Jacobs's account of the congress, an account which is extremely well drawn up, and which represents of course admirable facilities for giving us a description of what took place there. In the course of his paper he refers to a letter which was published in the *Medical Journal* here, and for the publication of which I am in a measure responsible. I think Dr. Jacobs exaggerates the effect — I hope he exaggerates the effect — which that letter may have had in diminishing the number of representatives from New England who attended the congress last summer. On the other hand, I should not be at all surprised if one might justly attribute in a measure to the publication of that letter, and to other similar statements, a part of the marked cordiality which was shown to visitors, and particularly to American visitors, although I have no question that under any circumstances Dr. Jacobs himself would have been well received. I think that it was high time that the better class of the French were brought to their senses. Liberty had degenerated into license there. I was in Paris about eighteen months ago, and I had an opportunity then to observe the remains of the exaggerated feeling which the French permitted themselves to entertain toward America and Americans during the progress of our Spanish War, and they had an excitability, a want of control, an absence of treating abstract political propositions or others where their interests and emotions are affected — of treating such in an abstract

fashion; the personality enters too much always, and they permitted it to enter in an excessive degree during our Spanish War, and subsequently for a considerable period during their differences with the English. And, as I say, in the exhibition of their feelings they had allowed liberty to degenerate into license, and had allowed the baser portion of the population, which is not a small one in Paris, to conduct itself in various ways in a manner which was at once disgusting, discreditable and disgraceful. If the treatment of foreigners and the sentiments shown toward foreigners had always been such in Paris and in France as they were at the time Dr. James Jackson and his fellow townsmen were there, in the thirties, about whom we all know well, and of whom I probably know as much as anybody, I doubt whether an indication would have arisen for the expression of such sentiments as it seemed necessary to express during this last summer. Again, it has been asked why Americans should concern themselves with incivilities to the English. There is one sufficient reason, if no more: the community of language. In a hostile atmosphere one English-speaking person is as bad as another.

I am glad that Dr. Jacobs, and those of our compatriots who were wise enough and fortunate enough to attend the congress, found everything so much to their satisfaction, and I am glad that even the weather adapted itself to their convenience and enjoyment. I have been in Paris more than once in July and August, but a cold wave during the first two weeks of August I have never encountered. I again congratulate Dr. Jacobs upon his experiences, and the society upon his felicitous manner of imparting them.

Dr. Bradford: I know I express the opinion of the Americans who were in Paris, and also of the profession of this country, in extending thanks to Dr. Jacobs for his energy in arranging the American representation at the Paris Medical Congress. What he states in regard to the congress is not only true, but more could have been said if his modesty had not restrained the full measure of his enthusiasm. A comparison between this congress and that in Berlin would suggest many interesting deductions. The Berlin and the Paris congresses were probably the most notable medical congresses that have ever assembled. At Berlin there was the feeling that the visitor was in the presence of a strong, active, virile, scientific movement. It was also impressed upon the visitor that what Dr. Shattuck would perhaps take exception to was not wanting, and unbecoming at times in an atmosphere of the purest science. In Paris the visitor could feel that he was the guest of a most cultivated nation, extending a hospitality that was not only cordial, but imperial in the quality, grace and richness of his entertainment. No one could enter the École de Médecine and find himself in the place where so much of the advance in medicine in this century had its origin without a certain inspiration. At the Sorbonne it is impressed upon the visitor that this great university where Chaucer and Dante went to learn, the place where from Abélard to Renan, Descartes and Bichat to Pasteur and Roux, that which would help humanity has been for centuries carefully and earnestly considered, is today one of the greatest of existing educational influences. It is to be remembered that this congress of seven thousand physicians was simply one of several congresses, and that at the same time the Sorbonne was entertaining there a congress of general education, higher and primary education, with delegates from everywhere in the world, and the thought suggested itself that perhaps from this educational Mt. Parnassus today comes the strongest movement for education that exists anywhere in any one locality. The great advantage of scientific congresses is to diminish prejudices. So much has been said as to the degeneracy of the Latin races that an exemplification of this might be expected by a visitor to Paris. The two hundred congresses which were held in Paris this summer in addition to the World's Exposition, the greatest and richest collection of human productions ever gathered, hardly justified such an opinion. On the contrary the feeling suggested itself that perhaps the Continental opinion had some justification, the Continental belief which regards the Anglo-Saxon and especially the American civilization as given over too much to material things on account of our great wealth, our great commercial and financial success, disregarding in a measure science and art, and not giving humanity the highest gifts of mental effort in proportion to our talents of energy and strength. It is folly to go to Paris to scorn. We must bow to the French in thanks for their great intelligence and activity as exemplified in the wonderful organization of this most remarkable medical congress. The society will, I know, join me in offering thanks to Dr. Jacobs for his kindness in coming here.

Recent Literature.

Medical Diseases of Infancy and Childhood. By Dawson Williams, M.D., Physician to the East London Hospital for Children. New (second) edition. Specially revised for America by F. S. Churchill, A.B., M.D., Instructor in Diseases of Children, Rush Medical College. In one 8vo volume of 538 pages, with 52 illustrations and 2 colored plates. Philadelphia and New York: Lea Brothers & Co. 1900.

This comparatively short book is, on the whole, fairly satisfactory. The author's point of view, however, seems that of ten or fifteen years ago rather than that of today. The strongest points in the book are the accurate and comprehensive clinical descriptions. They cannot fail to be most useful, especially to the beginner. The author has stated in his preface that pathological processes are essentially the same in children as in adults, and hence has given but little space to their description. In some instances it seems as if more would have been better. There is little tendency to make use of modern methods of diagnosis, the chief reliance being placed on symptomatology. This failure has been to a certain extent repaired by Dr. Churchill. Even he, however, has not taken up modern methods as thoroughly as he might have; for example, the leucocyte count is mentioned but twice as a means of differential diagnosis, and then superficially and inaccurately. Much space has been given to treatment, much of which is very good and all of which is suggestive. This must also prove of great assistance to the beginner. Too many drugs are mentioned, however, in the treatment of certain diseases,

in which they are certainly of but little value. There is a tendency also to polypharmacy.

The paper and print are good. The various diseases follow each other closely without any break in the text. The addition of a few pages would have avoided this crowding and added much to the appearance and clearness. The pictures are few and only mediocre. The arrangement of the various chapters is certainly a strange one. Diseases of the mouth are placed between the diseases of the heart and those of the upper respiratory tract. Tubercular meningitis is taken up under nervous diseases instead of with tuberculosis. Cerebrospinal meningitis, however, is properly classed with the acute infectious diseases.

The introductory remarks on the care of children are very good, and show the results of much practical experience. The chapter on the clinical examination of infants also contains many useful points which will be especially instructive to beginners. The chapter on the diseases incidental to birth is not so good. The part played by congestion in the causation of meningeal hemorrhage is not mentioned. The article on melena neonatorum is misleading. Dr. Churchill's explanatory note is much better. The chapter on food, except for the part written by Dr. Churchill, is rudimentary and far behind our present knowledge. The part written by Dr. Churchill is up to date and very good.

As would be expected in an English book, the chapters on the acute exanthemata are very good. The chapters on tuberculosis are, as a whole, pretty good. The article on tubercular peritonitis, however, is not up to the standard of the others on tuberculosis. The chronic ascitic form is not mentioned, and the fibrous form is not described, the caseating form alone being considered. The section on tuberculosis of the lungs is, on the contrary, extremely good.

The chapter on the diseases of the blood is incomplete and the descriptions, both of the symptoms and of the blood, poor. Leucocytosis, for example, is described under secondary anemia, and under splenic anemia is described secondary anemia with splenic enlargement rather than the true splenic anemia.

The chapter on dentition and the diseases of the mouth is especially good, as is also that on the diseases of the upper respiratory tract. Those dealing with the diseases of the lungs and pleura are also very good.

The chapters on the diseases of the gastro-enteric tract are not up to the standard of the rest of the book. No attempt has been made to separate the diseases of the stomach from those of the intestines, or functional diseases from organic. All the forms of diarrhea are inextricably mixed together so that the beginner could hardly get a correct idea of the different forms. This fault is redeemed to some extent by the reviser's notes, which are very much to the point, but because of the confusion elsewhere are somewhat difficult to apply. Infantile atrophy is classed among the chronic diseases of the gastro-enteric tract instead of as a disease of nutrition, and is given but one paragraph and no treatment.

The section dealing with the normal urine embodies the original researches of Dr. Churchill and contains much which is new to textbooks. In the chapters on the nervous system various symptoms and conditions have been put on a par with the true functional diseases and treated as such; for example, deafness due to inflammation of the middle ear has been treated as a disease of the nervous system. But one cause, gastro-enteric toxemia, is recognized for tetany. The articles dealing with the organic diseases of the nervous system are fair, while those treating of the skin are good.

As already stated, the book is, on the whole, fairly satisfactory and especially strong in clinical description. The annotations of Dr. Churchill add much to its value and lead us to hope that he may some time give us a book of his own.

Refraction, and How to Refract. Including Sections on Optics, Retinoscopy, the Fitting of Spectacles and Eye Glasses, etc. By JAMES THORINGTON, A.M., M.D., Professor of Diseases of the Eye in the Philadelphia Polyclinic and College for Graduates in Medicine, etc. Second edition. Pp. 301, with 200 illustrations, 13 of which are colored. Philadelphia: P. Blakiston's Son & Co. 1900.

The first edition of this work, published in November, 1899, was reviewed in these columns, and the fact that a second edition has been called for so soon would seem to show that the book may prove as popular as the work on "Retinoscopy" by the same author.

A Book of Detachable Diet Lists for Various Diseases. Compiled by JEROME B. THOMAS, JR., A.B., M.D., Instructor in Clinical Medicine, Long Island College Hospital, etc. Second edition, revised. Philadelphia: W. B. Saunders & Co. 1900.

This is a convenient list of diets, so printed and arranged that the physician may easily extract what he desires to prescribe in the way of food, freeing him from the necessity of writing out detailed directions. The only danger in such a plan is that the physician by degree loses initiative, but this after all may not be an unmitigated evil amidst the growing details of so-called general practice.

Insect Larvæ as Occasional Parasites in Man. By EHRICH PEIPER, M.D. Berlin: Louis Marcus. 1900.

This little book is an amplification of an article on the same subject in one of the German medical journals. It offers in convenient form an abstract of what is known of the action of larvæ on the skin and subcutaneous tissue, the mucous membrane of the mouth, nasal cavity and ear, and on the stomach and intestines. The writer has apparently made a careful search through the literature, and the book will be found most useful for reference. There is a complete bibliography appended.

Dermatohistological Technique. By MAX JOSEPH, M.D., and GEORGE LOEWENBACH, M.D. Second edition. Berlin: Louis Marcus. 1900.

The object of this book is to provide a guide both for the beginner in the histology of the skin, and for the more advanced investigator, and to furnish an abstract of all the more important technical methods. As no similar compilation exists, so far as we are aware, it should be welcomed as a real addition to dermatological literature. The fact that a second edition was demanded at the end of six months speaks for its success.

The International Textbook of Surgery. By American and British Authors. Edited by J. COLLINS WARREN, M.D., LL.D., Professor of Surgery in Harvard Medical School; Surgeon to the Massachusetts General Hospital, and A. PEARCE GOULD, M.S., F.R.C.S., Surgeon to the Middlesex Hospital; Lecturer on Practical Surgery and Teacher of Operative Surgery to the Middlesex Hospital Medical School, etc. Vol. II, Regional Surgery. Pp. 1,072, with 471 illustrations in the text, and 8 full-page plates in colors. Philadelphia: W. B. Saunders & Co. 1900.

This excellent volume fully justifies the expectations aroused by the publication of its predecessor (Vol. I), a review of which has already appeared in this JOURNAL.[1] It is the concluding volume of the work.

Its general characteristics, as regards presswork, illustrations, classification, indexing, etc., are similar to those noted in Vol. I.

It deals solely with regional surgery. The contributors are all men well known in this country and abroad. Many have written monographs of note, or have made extended investigation of the special subjects treated in the chapters assigned them by the editors. Particularly so are the writers of the chapters describing the surgery of the breast, appendix, hernia, ureter, kidney and ear. The articles devoted to military surgery, which includes a description of modern firearms and projectiles, to naval surgery, and to surgery and surgical operations in the tropics, make the work a thoroughly modern one, and are of especial interest at this moment on account of the attention which the events of the last two years have attracted to this branch of surgery.

The articles are all well written. As stated in describing Vol. I, the plan of paragraphing distinguishes the subdivision of subjects from the general text, and makes a book quite convenient for reference. The different articles contain the essential facts relating to the particular subject discussed that are found in modern surgical literature. Although some at first sight seem rather condensed, still, as the book is designed as a textbook, perhaps this is a feature to be commended rather than criticised.

The book represents work which is highly creditable to all concerned in its production.

On the Prevention of Eye Accidents Occurring in Trades. An Address Delivered at the Opening of the Section of Ophthalmology at the Annual Meeting of the British Medical Association, at Portsmouth, August, 1899. By SIMEON SNELL, F.R.C.S. (Edin.), Ophthalmic Surgeon to the Royal Infirmary, Sheffield; Professor of Ophthalmology, University College, Sheffield. Pp. 32, with 11 full-page illustrations. London: Ball, Sons & Danielsson, Ltd. 1900.

The author, living and practising in Sheffield, Eng., has naturally been much attracted to this subject, and writes from a larger experience than that of any confrère in any country in all probability.

The subject is treated forcefully, and means of preventing such accidents described and discussed. The little book is well worth the attention of all, whether physicians or laymen, interested in abating the dangers run by certain classes of workmen.

THE BOSTON

Medical and Surgical Journal

THURSDAY, JANUARY 10, 1901

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE RATIO OF PHYSICIANS TO THE POPULATION.

RECENT publications present an opportunity to learn the relative number of physicians to the population in the United States and in Germany, with a fair degree of accuracy, and to compare these numbers in the different States with each other.

Dr. Abbott's recent monograph, which was prepared for the Paris Exposition,[1] contains a table, the basis of which is "Polk's Register of Physicians in the United States." The relative figures were determined by comparing these figures with the population of each State as estimated for 1898, and may be considered as fairly correct, with the exception of Oklahoma and one or more new States in which the rate of increase was out of all proportion to that of former years.

The publication of a later edition of the "Register" in 1900 makes it possible to present on the following page a more accurate table, based upon the recent census of 1900.

From the following table it would appear that either the old aphorism that 1,000 inhabitants are required for the support of the average physician must be considered as out of date, or a large proportion of the profession are not earning a living, since the average for the United States at large as shown in the following table is 1 physician to each 655 inhabitants. Moreover the large annual product of the medical colleges is constantly tending to diminish this number of inhabitants to each physician.

An examination of the following table shows that California is the State which is most liberally supplied with medical men, the proportion there being 1 physician to 416 inhabitants, and the ratio in Colorado and Vermont is about the same, while the States which are the most sparsely supplied are South Carolina, North Dakota, North Carolina, New Mexico and

[1] **The Past and Present Condition of Public Hygiene and State Medicine in the United States; being No. 19 of the Monographs on American Social Economics, prepared for the Paris Exposition of 1900.**

Alaska, with respectively 1 to 1,123, 1,132, 1,189, 1,395 and 2,349 inhabitants.

These conditions are clearly illustrated for the year 1898 by means of a chart in the pamphlet referred to. The two tables for 1898 and 1900 do not present very striking differences except in the States of Iowa, Kansas and Nebraska, the reasons for the difference being apparently due in the two former States to an unusual increase in the population, and in the latter to an unusual increase in the number of physicians.

Turning now to Germany, an entirely different condition is evident as shown by the recent publication of the Imperial Board of Health of the German Empire.[2] In that country, three enumerations of the physicians have been made at intervals of eleven years, one in 1876, one in 1887, and the last in April, 1898. The last enumeration was very comprehensive and included all persons employed in connection with the care and treatment of the sick, either in private practice or in hospitals or other institutions. The circular calling for information was issued by the Imperial Board of Health of Germany and included the enumeration of the following persons:

Regular practising physicians: (*a*) Physicians in private practice; (*b*) physicians in institutions; homeopathic physicians; military and naval surgeons; other "approved" practitioners, including surgeons and country doctors; dentists; dentists' assistants; nurses, masseurs, etc.; veterinary surgeons, civil and military; midwives.

The foregoing are still further classified quite minutely.

Two excellent maps are also presented, showing the distribution of physicians in the German Empire.

In the empire at large the number of physicians had increased from 15,284 in 1887 to 24,725 in 1898, or more than 56%, while the population had increased only 14%. This last enumeration shows that the ratio of the number of physicians to the population in Germany is very much less than that which prevails in the United States, since in the German Empire there was in 1898 only 1 physician to each 2,114 inhabitants, while in the United States at the same time there was 1 for every 647 inhabitants.

[2] Medizinal-statistische Mittheilungen aus dem kaiserlichen Gesundheitsamte, Bd. vi., H. 1, Berlin, 1899.

The German documents also give a further classification in detail according to the density of the population of 1,005 districts.

In districts having more than 20,000 (cities), the number of the physicians had increased from 6,648 in 1887 to 12,651 in 1898, or 90%, the population increasing meanwhile only 48%.

In districts having from 5,000 to 20,000 inhabitants, the number of physicians had increased from 3,295 to 4,256, or 29%, the population increasing only 19%.

In the smaller districts having less than 5,000 in each, the physicians increased in the eleven years from 5,881 to 7,818, or 33%, while the population remained nearly stationary.

The number of homeopathic physicians in the German Empire is stated as 240, or less than 1% of the whole number of practitioners.

The veterinary surgeons were 3,813 in number, and are compared with the class of patients whose ills they are called upon to treat, there being in the German Empire 1 veterinary surgeon to every 1,240 horses, and 5,677 head of cattle.

An examination of the maps and accompanying tables shows that both physicians and midwives are distributed most liberally in Bavaria and the districts along the Rhine, while the districts which are most sparsely supplied are those of Northeastern Prussia and the Russian border.

PHYSICAL CULTURE.

HOWEVER it has come about, whether through the increasing devotion to athletics or for other reasons, it is clear that physical culture in the broad sense is occupying a more and more conspicuous place in education. This must certainly be regarded as an unqualified good, and chiefly because it is based on a system which may justly lay claim to a scientific basis. Physical training is gradually but surely becoming rational; the excesses to which competitive athletic events are always likely to lead will surely be modified by a knowledge of the physiological effects of training. Both directly and indirectly the present zeal for physical culture, designed not only to make the strong stronger, but also the weak strong, is doing much to-

ward the general development of the masses of young men and women. Institutions have, however, been slow in completely recognizing the dignity of this branch of education by establishing a definite department under the jurisdiction of a competent head. It is, therefore, of particular interest at this time that the Massachusetts Institute of Technology has taken action to install a new department devoted to physical culture. The formal announcement of this fact was made by President Pritchett at the annual dinner of the Alumni Association recently held in Boston. It was announced that the corporation had voted to give the land for the building, which is to be a memorial to the late General Walker, former president of the Institute. In this building is to be established the new department, provided the necessary endowment fund can be raised, under the charge of "a man who shall be able to do for the physical side of the students what the heads of other departments now do for the intellectual side." It is sincerely to be hoped, and there is small doubt that the hope will be realized, that this somewhat unique department of a great educational institution may be generously maintained. It will prove not only of service to the institution with which it is connected, but will undoubtedly serve as a stimulus toward the establishment of similar departments elsewhere. The time is undoubtedly ripe for just this line of work, and we are gratified to see that so worthy a memorial is to be erected to the lamented president of our most conspicuous technical school.

The tendency everywhere apparent is further shown by the recent meeting in New York of the various physical directors of the larger gymnasiums connected with our schools and colleges. The strength which comes from organization will no doubt show itself by renewed and systematic attempts toward raising the standard of this department of school and university work. The very general introduction of physical training into the public schools has already been productive of much benefit to the pupils. The idea, recently suggested for the Brookline, Mass., schools, of giving special treatment to pupils of imperfect physique, is also unquestionably a step in the right direction. The whole movement toward bringing about a symmetrical physical development, beginning with the very young, is in every way commendable.

In the hands of competent men there is small danger of attaching undue importance to this fundamental branch of a child's education.

MEDICAL NOTES.

ABSTRACT REPORT OF THE COMMITTEE ON THE LIBRARY OF THE NEW YORK ACADEMY OF MEDICINE. — Number of books in the library, November 30, 1900, 89,000 volumes, duplicates, 36,105 volumes, included; books added during year, not including duplicates, 3,649 volumes; in the circulating department 971 books and 832 journals were issued to 194 readers; 11,520 readers have registered during the year in the reading room, and probably many others have used the library but not registered. The library is growing rapidly, the additions annually for the last four years being at least 3,500 volumes a year (in 1898, when the library of the New York Hospital was donated to the academy, 7,000 volumes) without including duplicates. Nine hundred and ninety-one journals in many languages are on file, and add 1,135 bound volumes this year to the shelves. Including the duplicates, the natural growth amounts to about 5,000 volumes, and at this rate there is only space left in the stack room for five years more. More space for the library is urgently needed, and it will be difficult to find this space in the present building. At present there are 13,430 feet of shelving available, of which less than 3,000 are unoccupied, and 600 feet of shelving are needed annually for the natural growth in new books. The labor of taking charge of this large collection of books will require an increase in the librarians' staff this coming year. More money is urgently needed, both for the purchase of books and for the running expenses.

DEATH OF AN ARMY NURSE. — Mrs. Anna Morris Holstein, a famous army nurse in the Civil War, widow of Major William Hayman Holstein, has recently died in Redhill, near Norristown, Pa., aged seventy-six. From 1862 until the close of the war Mrs. Holstein was engaged in the hospital service, and after the battle of Gettysburg she was matron in chief of a hospital in which 3,000 seriously wounded men were looked after. It is said to have been largely through her influence that Washington's headquarters at Valley Forge were purchased, restored and made accessible to the people.

PLAGUE IN VLADIVOSTOCK. — The reports of an outbreak of plague at Vladivostock are confirmed. There had been up to January 4th 19 cases, of which 15 were fatal. Owing to a recrudescence of plague at Smyrna, a quarantine has been imposed by Turkey and Greece on arrivals from that port.

TWENTY-FIVE THOUSAND DEATHS FROM PLAGUE. — Lord Curzon, Viceroy of India, has stated that since the appearance of the bubonic plague, in 1898, 25,000 deaths from the disease have occurred in the Mysore State.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, January 9, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 192, scarlatina 55, measles 43, typhoid fever 24.

BOSTON MORTALITY REPORT. — The number of deaths reported to the Board of Health for the week ending January 5th was 239, as against 283 the corresponding week last year, showing a decrease of 44 deaths, and making the death rate for the week 22.2. The deaths from consumption were 24, pneumonia 34, whooping cough 2, heart disease 22, bronchitis 10, marasmus 4. There were 14 deaths from violent

causes. The number of children who died under one year was 38, under five years, 64, persons more than sixty years 54; deaths in public institutions 88.

ITEMS IN BOSTON LOAN BILL. — The mayor has approved, among others, the following items of the loan bill, recently submitted to him: Hospital Department (Boston City Hospital), $100,000 for new surgical out-patient building; $120,000 for a ward for patients requiring isolation; $30,000 for a new wing at the Long Island Hospital; $20,000 for a nurses' home at the same institution; $75,000 for new building at the Boston Insane Hospital.

BOSTON MEDICAL LIBRARY. — The new building of the Boston Medical Library will be open for inspection of the public on Saturday, January 12th, 11 A.M. to 5 P.M. The dedication exercises, for which invitations have been issued, will take place in the evening.

NEW YORK.

HEALTH STATISTICS, 1900. — The following is a portion of a statement given out January 4th by Dr. Tracy, Registrar of Records in the Health Department: "The year set in with a high mortality, due to the recurrence of influenza, which began its ravages in December, 1899, and did not disappear until the following June. The epidemic culminated in March, but its decline was slow, and during the first five months of the year the deaths in the city numbered 4,987 more than those of the corresponding months of 1899. Of this increase, 2,053 were caused by acute inflammatory diseases of the organs of respiration, and the remainder, in all probability, by the depressing effect of the prevailing epidemic upon the course of other diseases. During the summer months the hot weather was much more severe and prolonged than in 1899, and as a natural consequence there were more deaths directly or indirectly caused by the heat. There were 294 deaths from sunstroke, against 141 in 1899, an increase of more than 100%, and yet the total excess of deaths in July, August and September of 1900 over 1899 (notwithstanding the increased population) was only 806, less than 5%, and from diarrheal diseases only 408, about 17%. There was an increase of about 50% in the deaths from measles, 25% from typhoid fever, and 10% from diphtheria and croup, these being no more than the normal variations to be expected from year to year, sometimes up and sometimes down, the totals in no case being large. There were 12 deaths from smallpox, against 18 in 1899." The death rate for 1900 was 20.53, as against 19.47 in 1899.

SMALLPOX. — The last monthly bulletin of the State Board of Health, issued January 3d, devotes considerable attention to the subject of smallpox. It says in part: "During the last three years we have had considerable experience with smallpox, commencing with an importation, in 1898, by a travelling theatrical troupe, among whose members the disease existed undiscovered until twenty localities in the western part of the State had been visited, and, as a result, smallpox was distributed in fourteen counties; not less than 320 persons took the disease, and a year passed before it ceased to exist. During this current year [1900] smallpox has been brought to seventeen places from outside. Now, towards the close of November, prior to which the State had been free for three months from this disease, a repetition of the experience of 1898 on a smaller scale is threatening, in the appearance of another travelling troupe of colored minstrels from the South, in whose personnel smallpox has been discovered after having exhibited at eight places in the eastern part of the State, in three of which, Albany, Schenectady and Gloversville, an outbreak has followed. There has also been a considerable outbreak in a locality in New York City which this troupe touched in passing. The present comparative immunity of this State from smallpox is chiefly due to very general vaccination, secured by health authorities, especially in places where the disease has developed, and more widely by the operation of the law, now several years in effect, requiring the vaccination of school children."

MORTALITY STATISTICS FOR NOVEMBER. — The Health Department's reports show a reduction in the city's mortality for November as compared with October, the death rate in the latter month being 17.54 against 16.82 in November. This is also a decrease from the death rate in November of 1899, which was 17.63. The most marked decline is in the class of diarrheal diseases, the weekly average of deaths from which was 21.75 in November and 51 in October. The weekly average of deaths from phthisis decreased from 169.25 to 145.5; of deaths from typhoid fever, from 24.5 to 21.75; of deaths from whooping cough, from 5.25 to 4.5, and of deaths from measles, from 2 to 1.25. On the other hand the weekly average of deaths from pneumonia increased from 122.5 to 155.25, the mortality from this disease thus exceeding that from phthisis. The weekly average of deaths from bronchitis increased from 26.25 to 37.75 and there was also a very slight increase in the mortality from diphtheria and cancer. The weekly average of deaths from scarlet fever was exactly the same in the two months. Three deaths in the month of November are attributed to influenza, this being the first time that this disease has appeared as a cause of death since last spring.

PAVILION FOR CONTAGIOUS DISEASES, RANDALL'S ISLAND. — At a meeting of the Board of Health held December 27th a resolution was adopted favoring the construction of a pavilion for contagious diseases in connection with the Randall's Island Hospital for Children, under the care of the Charities Department, and a committee was appointed to confer with Commissioner Keller, of that department, in regard to the matter. It appears that among children suffering from contagious affections (principally measles) who were transferred to the North Brother Island and Willard Parker Hospitals, the mortality has of late

been excessive. Out of 32 such patients no less than 18 died, and it is believed that the risks will be greatly diminished if this class can be treated in wards in the vicinity of, but at a safe distance from, the institution on Randall's Island.

Annual Meeting of American College Physical Directors. — The annual meeting of American College Physical Directors was held on December 28th and 29th at Columbia University. The following reports by the chairmen of a number of committees appointed last year were received: On the Advisability of Determining the Physical Condition of Candidates for Gymnastic and Athletic Exercise, Dr. Jay W. Seaver, of Yale; Strength Tests and Inspection of Instruments, Dr. Dudley A. Sargent, of Harvard; On the Adoption of Uniform Terminology and Nomenclature for Gymnastic Exercise, Dr. W. G. Anderson, of Yale; Credit for Gymnastic Training in College Work, Dr. W. A. Lambeth, of the University of Virginia; On the Relationship between Gymnastics and Athletics, Dr. W. G. Anderson, of Yale.

The Benefits of Modern Surgery. — Among the speakers at the annual meeting of the New York Orthopedic Dispensary and Hospital on January 4th were Bishop Potter and Governor Roosevelt. The former, in speaking of the benefits of modern surgery, stated that twenty-five years ago while in the Yosemite he met with an accident causing what he supposed at the time was a sprained ankle, and which had caused him more or less pain, attributed to gout, ever since. Within the past year he had found, through an x-ray examination at St. Luke's Hospital, that the trouble was in reality an ununited Pott's fracture.

Gift to the New York Ophthalmic and Aural Institute. — Dr. Herman Knapp has conveyed, as a gift to the New York Ophthalmic and Aural Institute, the two adjoining buildings on Twelfth Street which have been occupied for many years by the institution. It was founded by Dr. Knapp in 1869, and in addition to a dispensary and hospital has maintained a school of ophthalmology and otology.

New Ward for Tuberculosis at Bellevue Hospital. — A new ward, known as the Tuberculosis Pavilion, and accommodating 200 patients, was opened at Bellevue Hospital on January 1st, with three graduate nurses in attendance. There is still a considerable upheaval going on at Bellevue, growing out of the developments of the Hilliard case, and a vast amount of "investigating" is being done.

A Centenarian. — Mrs. Ann Jane Slote, of Brooklyn, was the first centenarian to die in 1901, her death occurring on January 2d. She was born in Ireland on July 12, 1800, and thus lived in three centuries. A son, Daniel, who died in 1882, was the "Dan" of Mark Twain's "Innocents Abroad."

Decrease of Smallpox. — In New York City fewer cases of smallpox have been reported during the past week than in the previous week, and as much as three days elapsed without a single new case. It is estimated that at least a million persons have been vaccinated since Thanksgiving.

New York State Medical Association's Journal. — This association has undertaken the publication of a monthly journal instead of annual transactions. The first number has been received.

Governor Odell Advocates Economy. — In his first annual message Governor Odell has advocated a number of radical changes, principally on the score of economy.

Opening of New Gouverneur Hospital. — The formal opening of the fine new Gouverneur Hospital of the Charities Department took place on January 5th.

Miscellany.

THIRD PAN-AMERICAN MEDICAL CONGRESS.

The Third Pan-American Medical Congress will be held February 4th to 8th, inclusive.

The steamer *Seguranza*, of the Ward Line, leaves New York, January 30th, arriving in Cuba on February 3d, the day before the beginning of the congress. The new Ward Line steamer *Morro Castle*, holding 135 cabin passengers, leaves Havana on February 9th, reaching New York February 11th. The round trip is $70. Any one going via this route will be absent from New York twelve days. All information regarding transportation may be had from Dr. H. L. E. Johnson, 1402 L Street, N. W., Washington, D. C. Any of the delegates going down by the Ward Line who desire it may, by a supplementary payment of $25, return via Santiago. This trip will take from ten to twelve days, during which time the passengers live on the ship and have their meals there if they so desire. The party goes from Havana by rail to Cienfuegos in one afternoon, there taking the steamer to Santiago and from Santiago to Nassau in the Bahamas, and from Nassau to New York. The stay in these different ports will be for a day or more.

An auxiliary committee of ladies will assist in the entertainment of ladies accompanying delegates. The best hotels in Havana are the Telegrafo, Mascotte, Inglaterra and Pasaje. Rates $3.00 to $5.00 per day for board and room, American plan, the prices depending on the room.

General Wood, the Governor-General of Cuba, formerly surgeon in the United States Army, will give a reception to the delegates, probably the day before the opening of the congress. He will also give orders that the fortifications of the island be shown to the delegates.

The sessions of the sections of the congress will begin on the morning of February 4th in the halls of the university and institute. In the evening the formal opening ceremonies of the entire congress, a general session, will take place at the Tacon Theatre, at which the various representatives of the different countries will be introduced, and speeches of welcome will be made by the officers of the congress as well as by the civil authorities.

According to present indications, it is judged that there will be about 1,500 delegates at the congress. Of these, probably 500 will be Cubans, 300 or 400 from the United States, 200 from Mexico, 100 from Argentine Republic and Uruguay, 50 from Brazil, 50 from Venezuela and as many more from Colombia and other countries.

It is requested that from this time on, titles of papers should be sent both to the general secretary of the congress, Dr. T. V. Coronado, 105 Prado, Havana, and to

the assistant U. S. secretary, Dr. Ramon Guiteras, 75 West 55th Street, New York City, in order that they may be entered in the final programme.

It is also requested that all physician delegates intending to go to Havana send their names to Dr. Guiteras, in order that he may determine how many will be present from this country.

Obituary.

GEORGE G. TARBELL, M.D.

IN the death of Dr. George Grosvenor Tarbell on December 31, 1900, the communities in which he lived, Boston and Lincoln, lost a most valuable citizen who was faithful in an extraordinary degree to all the duties of citizenship; the medical profession a member who had filled in a marked manner many posts of honor. He graduated from Harvard College in the Class of 1862, entered the Harvard Medical School at once and graduated from it in 1865, having been one year of that time a medical interne at the Massachusetts General Hospital.

In response to an urgent call from Governor Andrew for surgeons in the Civil War, he became assistant surgeon and later surgeon of the Third Massachusetts Cavalry and served to the close of the war. He was a member of the Loyal Legion. In May, 1866, he began practice in Hingham, but removed to Boston in 1867. In April, 1868, he was appointed physician to out patients at the Massachusetts Hospital, and visiting physician in 1873. Years of most conscientious service he gave to the hospital; his advice and counsel were always valued by his colleagues. In the prime of his life, and ripe with experience and study of his cases, he resigned in 1891, not because he was weary in the service, but that the large clinical material in his wards could thereby be used in teaching the students of the Harvard Medical School, of whose teaching board he was not a member. He was then appointed by the trustees a consulting physician, which position he held at the time of his death. For many years he was one of the trustees of the Lincoln Public Library, whose fine building was given to the town by his uncle, Mr. George Grosvenor Tarbell, in 1884. To this institution he gave faithful and efficient service, and was president of the Board of Trustees at the time of his death.

Not alone in the practice of his profession was Dr. Tarbell a valued counsellor. Years of his life were given to the Massachusetts School for the Feeble-Minded. He became assistant superintendent of the school in January, 1878, and resigned in 1883. He was the executive head of the school for that period. He brought new life to the school; buildings were repaired, new school rooms and dormitories were built and an entirely new standard of work was established. In his early reports he strongly advocated the removal of the school from South Boston to the country. One year after his resignation as assistant superintendent he was made president of the Board of Trustees. Largely through his efforts the present site of the school at Waltham was secured by the State in 1886. The location was practically selected by him. His time and thought were given liberally to the preparation of the plans for the new buildings. He watched and directed every detail of arrangement and construction. Dr. Fernald, the present superintendent, writes: "I cannot express what Dr. Tarbell was to the school. His intimate knowledge of the 600 inmates and 120 officers and employés was such that he could call most of them by name. . . . Few of his friends knew how much time and thought he gave to the school. . . . He had attended every Christmas festival since 1878, except one when he was himself sick. The grief and sorrow of the unfortunate children at his death was most touching. . . . In his death they have lost their best friend."

The present institution, with the farm at Templeton, is a monument to his good judgment and painstaking care.

Correspondence.

THE ARMY BILL AND THE MEDICAL DEPARTMENT.

CINCINNATI, O., December 29, 1900.

MR. EDITOR: — Permit me through your columns to call the attention of the members of the American Medical Association to the fact that there is at present pending in Congress certain proposed legislation that seriously disturbs the present status and efficiency of the medical corps of the United States Army.

The proposed law is entitled, "An Act to Increase the Efficiency of the Military Establishment of the United States" (Senate Bill 4,300), and in a very general way modifies the existing organization of the army, while at the same time it provides for a damaging and offensively invidious discrimination against the medical corps. This fact is shown in the following particulars, namely: (1) It decreases the percentage composition of the corps in the grades of colonel from 3.1% to 2.4%; (2) it decreases the percentage composition of the corps in the grade of lieutenant-colonel from 5.2% to 3.7%; (3) it decreases the percentage composition of the corps in the grade of major from 26% to 18.6%; (4) it increases the percentage composition of the corps in the grade of assistant surgeon with the ranks of captain and first lieutenant from 65% to 74.7%.

The significance of these proposed changes can be understood when it is remembered that even under the existing law it requires more than eighteen years to reach the grade of surgeon with the rank of major, while under the proposed law it will require, at least, twenty-five years to reach the same grade and rank. With this fact reduced to a mathematical demonstration, the inevitable result will be (1) that the most worthy young men will not apply for commission, and (2) that the relatively less worthy men, who do enter the service, discouraged by the certain impossibility of reasonably prompt promotion, will resign, leaving their places to be filled by untrained and consequently less efficient men. The ultimate disaster from this contemplated change, however, will consist not alone in a lowered status of the medical service, but in (1) increased disease and death rate among the men; (2) a diminished and otherwise weakened force in the firing line, and (3) a material augmentation of the pension roll.

In view of the foregoing facts, and, in view of the fact that every other corps of the army is better graded than is the medical, every member of the American Medical Association and every member of the medical profession, is hereby earnestly solicited to send at once to his United States senator and congressman an urgent and emphatic protest against the proposed provisions in Senate Bill 4,300, relative to the medical corps of the United States Army.

(Signed) CHAS. A. L. REED, M.D.,
President American Medical Association.

[The JOURNAL has already referred to the question in an editorial, December 20th, page 643.— ED.]

CLIMATE IN PULMONARY TUBERCULOSIS.

BOSTON, January 4, 1901.

MR. EDITOR: — Since it has become evident that patients in the early stages of pulmonary tuberculosis may recover in any climate by proper hygiene and treatment, especially by outdoor life, and more especially in sanatoria, it seems as if there was danger that the climatic factor in treatment be overlooked or disregarded.

This, it seems to me, is unfortunate, for if there is any climate in which patients formerly recovered by simple

residence with little or no change in their daily life or occupation, it is certainly reasonable to infer that with modern methods of treatment they will recover more quickly and surely in that climate than if these methods were employed in one of poor conditions.[1]

Therefore I think that while we can encourage poorer patients in the hope that they may recover at or near home by entering a sanatorium or even simply by leading an outdoor life, we are not doing our duty to those who can afford it, if we do not advise them to put themselves in the very best climatic conditions known, namely, especially dry air and sunshine.

Although in their enthusiasm over the results of sanatorium treatment in what would be designated as poor climates some heads of institutions have gone so far as to say that they believe that dryness or moisture has nothing to do with the arrest of the disease, I think that the evidence is to the contrary. Sunshine is still considered desirable by all, and a climate with two or three times as many sunshiny days in a year as another must, other things being equal, be superior. The only satisfactory test of the real comparative value of climatic factors will come when sanatoria shall be established with exactly the same rigid rules of admission and the same methods of treatment all over the world, in what have been considered the best climates as well as in the poorest.

If we know that for any reason a patient cannot put himself in the best possible climatic conditions, the subject need not be mentioned to him, but if we know that he can do so, the best course can be none too good to advise in treating this still very formidable disease. I have seen many recoveries from pulmonary tuberculosis under all conditions, at home with or without change of mode of life or occupation, and in all kinds of health resorts and institutions, but for quickness and thoroughness of recovery in properly selected early cases nothing in my experience approximates that which occurs in dry, sunshiny climates.

While I usually mention several alternate plans to a tuberculous patient, by adopting either one of which a possible arrest of the disease may be brought about, I state very decidedly my opinion of their relative value in his case, and throw the responsibility of choosing anything but the best upon him. He should at least be offered the best.

It should be borne in mind also that there are many delicate patients, especially those with advanced disease, to whom outdoor treatment in a rigorous climate may mean great suffering.

Yours respectfully,
FREDERICK I. KNIGHT, M.D.

[1] In using the statistical results of sanatorium treatment for comparative purposes, it must be borne in mind that some sanatoria receive only the most carefully selected incipient cases, and that the percentage of cures among such patients cannot properly be compared with that in institutions or health resorts where patients in all stages of the disease are received.

OCULISTS AND OPTICIANS.

MEDFORD, MASS., November 23, 1900.

MR. EDITOR:—Several years ago, laws were enacted pertaining to the "Regulation of the Practice of Medicine within the Commonwealth of Massachusetts"; and even though we observe the enforcement of said laws by the Board of Registration of Medicine to a degree of merit, it would seem, however, that such laws have no existence, when we see the daily advertisements of the would-be specialists whose practice consists in the treatment of the optics.

Opticians have ventured into the field, advocating their competency (?) to examine the eyes, and assume to correct the errors of refraction without any knowledge of the anatomy of the eye. Department stores, also, have fallen into the line, adding further pretence and quackery to an innocent public; which is as absurd as it is ridiculous, for the simple reason that neither the optician nor the vender at the department store have any training in the knowledge of diagnosis relating to the science of opthalmology wherewith to ascertain the conditions of the eyes and the eyesight; and no person is fitted or competent for such a responsible practice other than he who has fulfilled the requirements of a reputable college or university, and obtained the degree of M.D., and devoted special study to ophthalmology.

This is a serious matter, to which I have applied much attention during the past two years; and during the intervals of my investigation, I have met many subjects who have been duped by opticians, peddlers and department stores, whose eyes have been almost ruined from the ill effects of improper lenses, which upon the day of purchase appeared to be correct.

To the oculist alone belongs the propriety, professionally and legally, to examine the optics, and to prescribe the proper remedy which will be the result of his diagnosis. On the other hand, the part of the optician is simply a mechanical procedure, and to supply glasses, according as the physician may prescribe them for his patient.

The physician by his skill and knowledge of ocular therapeutics should always be the proper counsel to approach to realize the best results when there appears to be trouble with the eyes.

Medical authority emphasizes the importance of consulting the oculist, and not the optician, in all matters pertaining to the optics, and it is not generally considered that there is an absolute distinctive difference between the oculist and the optician which should be carefully dealt with.

This is an instance which, for the protection of the public, appeals to the colleges of pharmacy for immediate investigation, and to proceed to the inauguration of the requirements in the study fitting graduates as opticians, as well as pharmacists; and an eligible course cannot fail to involve the sanction and co-operation of the medical profession universally, and the hearty approval of all mankind.

History tells us that it was not until the year 1854 that any attempt was made by the medical profession to estimate visual power. The result of the problem led to more persevering attainments, until finally a science has developed through the diligent study of specialists, who by their fertile brains have become authors, and merited fame throughout the world, and given to our colleges and universities many volumes of valuable textbooks, treating exhaustively upon the subject of ophthalmology.

See to it, then, that this matter is dealt with as as it should be, and, if necessary, let there be legislative means established to restrict peddlers, opticians and department stores from trifling with the optics by prescribing eyeglasses or to attempt to offer any support to aid defective vision.

Superintendents of public schools in many of our cities and towns have interested themselves most creditably in the importance of observing the impaired sight of pupils by the co-operation of teachers in the respective grades; and if there be any among them with abnormal vision they are at once directed to consult a competent physician or oculist to obtain the remedy and necessary assistance for correct vision.

The optician is not recognized other than in his proper sphere when he is called upon to supply lenses as per prescription. Therefore, I trust that what I have written will at once awaken an interest for the individual care, thought and study that finally will result in a protection against unscrupulous quackery, and be endorsed for the public good.

Would it not be well for practitioners in pharmacy to review this subject as a very important adjunct, and express their views to encourage the faculty at the Massachusetts College of Pharmacy to become interested, pursuant to adopting a course of study for pharmacists to become opticians?

Respectfully,
JAMES E. MCKEON,
Pharmacist and Optician.

METEOROLOGICAL RECORD

For the week ending December 29th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Deaths reported 2,121; under five years of age 529; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 485, acute lung diseases 396, consumption 248, diphtheria and croup 74, typhoid fever 66, diarrheal diseases 36, whooping cough 17, scarlet fever 12, cerebrospinal meningitis 7, measles 6, erysipelas 6.

From whooping cough New York and Pittsburg 5 each, Boston 3, Clinton 2, Chelsea and Everett 1 each. From cerebrospinal meningitis Worcester 3, New York 2, Boston and Gloucester 1 each. From scarlet fever New York and Boston 4 each, Baltimore, Pittsburg, Worcester and Somerville 1 each. From measles New York 5, New Bedford 1. From erysipelas New York 2, Lowell, Haverhill, Chelsea and Newton 1 each. From typhoid fever Pittsburg 21, New York 19, Boston 12, Baltimore 4, Worcester 3, Providence 2, New Bedford, Springfield, Holyoke, Taunton and Chicopee 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending December 15th, the death rate was 16.8. Deaths reported 3,744: acute diseases of the respiratory organs (London) 349, diphtheria 77, whooping cough 68, fever 58, measles 49, scarlet fever 42, diarrhea 34.

The death rates ranged from 8.6 in Norwich to 22.2 in Manchester; Birmingham 16.5, Bolton 21.3, Bradford 16.3, Cardiff 12.9, Croydon 11.9, Derby 15.0, Gateshead 20.0, Halifax 12.4, Hull 19.9, Leeds 17.5, Liverpool 20.0, London 16.5, Newcastle-on-Tyne 17.4, Nottingham 22.1, Plymouth 16.8, Portsmouth 13.6, Salford 17.7, Sheffield 18.7, Swansea 15.8, West Ham 12.6.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 5, 1901.

R. P. CRANDALL, surgeon, detached from the U. S. training ship "Constellation," upon reporting of relief, ordered to temporary duty in connection with recruiting at Milwaukee, Wis., and then home to wait orders.

W. A. MCCLURG, surgeon, detached from the "Indiana" and to Naval Training Station, Newport, R. I., as the relief of Surgeon R. P. CRANDALL.

J. M. BRISTER, assistant surgeon, ordered to the "Independence," January 13, 1901.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING JANUARY 3, 1901.

PURVIANCE, GEORGE, surgeon. Relieved from duty at Baltimore, Md., and directed to proceed to Washington, D. C., reporting at the bureau for duty. December 29, 1900.

WERTENBAKER, C. P., passed assistant surgeon. To proceed to Shreveport, La., for special temporary duty. December 28, 1900

STIMSON, W. G., passed assistant surgeon. To proceed to Denver, Col., for special temporary duty. January 1, 1901.

BROWN, B. W., passed assistant surgeon. Relieved from duty at Cape Charles Quarantine and directed to proceed to Baltimore, Md., and assume command of the service, relieving Surgeon GEORGE PURVIANCE. December 29, 1900.

WILLE, C. W., assistant surgeon. To assume temporary command of Cape Charles Quarantine, relieving Passed Assistant Surgeon B. W. BROWN. December 29, 1900.

AMESSE, J. W., assistant surgeon. On being relieved by Assistant Surgeon L. P. H. BAHRENBURG, directed to proceed to Manila, P. I., and report to chief quarantine officer for duty. January 2, 1901.

LLOYD, B. J., assistant surgeon. Granted leave of absence for eighteen days from December 11th. January 3, 1901.

BAHRENBURG, L. P. H., assistant surgeon. Bureau order of December 27, 1900, directing Passed Assistant Surgeon Bahrenburg to proceed to Manila, revoked; and directed to proceed to Honolulu, H. I., reporting to the chief quarantine officer for duty. December 31, 1900.

BREADY, J. E., acting assistant surgeon. Granted leave of absence for four days from January 2, 1901. December 28, 1900.

KOLB, W. W., hospital steward. Granted leave of absence for thirty days from January 29th. January 2, 1901.

OLSEN, E. T., hospital steward. Granted leave of absence for five days. January 2, 1901.

CASUALTY.

A. R. BOOTH, acting assistant surgeon, died at Shreveport, La., December 27, 1901.

SOCIETY NOTICE.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The Section for Clinical Medicine, Pathology and Hygiene will hold a regular meeting on Wednesday, January 16, 1901, at the Boston Medical Library Building, 8 The Fenway, at 8 P. M. The meeting will be held in Sprague Hall, in the rear of the first floor of the building.

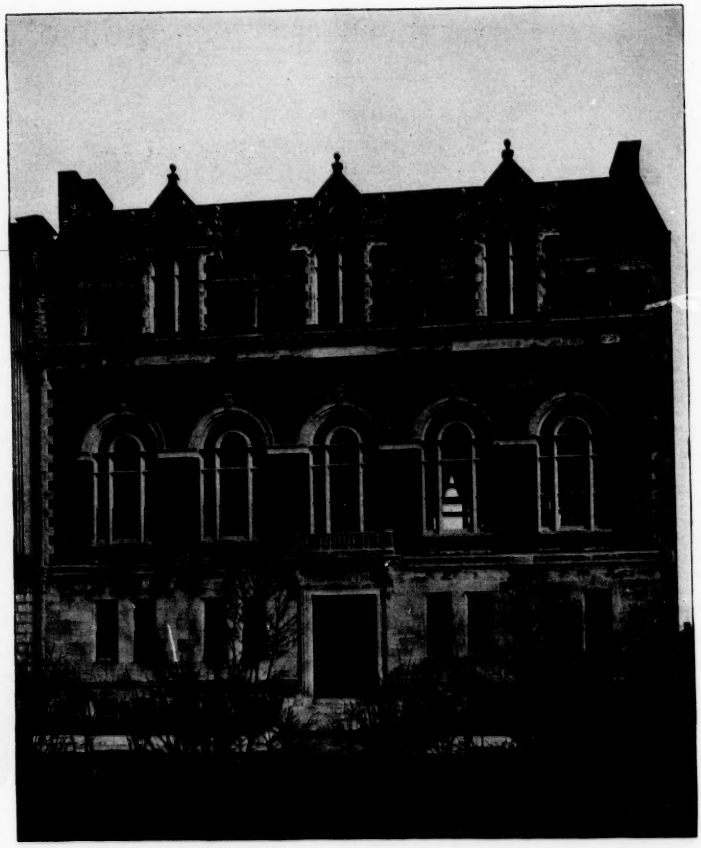
At 8 o'clock: Drs. F. W. White and Maynard Ladd will present a paper entitled "Whey Cream Mixtures in Infant Feeding."

At 8.15 o'clock: Drs. W. N. Bullard and C. W. Townsend will present a paper entitled "Convulsions in Children." Discussion by Drs. Rotch, Wentworth and Morse.

HENRY F. HEWES, M.D., *Secretary.*

RECENT DEATH.

R. V. K. MONTFORD, M.D., clerk of the Board of Education and superintendent of the public schools of Newburgh, N. Y., died on December 28th. He was born in Fishkill village in 1835 and served as surgeon of the 124th Regiment, New York Volunteers, throughout the Civil War. He had been connected with the Newburgh schools for nearly thirty years.



THE NEW BUILDING OF THE BOSTON MEDICAL LIBRARY.

Addresses.

DEDICATION

OF THE

NEW BUILDING OF THE BOSTON MEDICAL LIBRARY.[1]

ADDRESS

BY

DAVID W. CHEEVER, M.D., LL.D.,
President of the Boston Medical Library Association.

MEMBERS OF THE BOSTON MEDICAL LIBRARY, OUR INVITED GUESTS, LADIES AND GENTLEMEN: — By the liberality of many citizens, women as well as men, whose gifts we gratefully acknowledge, and by the free offerings of our professional brethren, we have erected this commodious and safe depository for our medical library. It is with a peculiar feeling of thankfulness that I officially welcome here the physicians of Boston and of New England. The object for which we have striven is so vital to our welfare that a certain solemnity is appropriately mingled with our gratitude. Over and over again, in these later years of financial prosperity, have we seen vast schemes of benevolence, of religion and of education begun and finished promptly by the munificence of a single wealthy citizen. Such has not been our good fortune. We have received but one large gift and that from a lady who wishes to remain unknown.

"*Inter tedia et labores*," literally, have the doctors toiled to make this library and to give it a safe and suitable building. Our librarian will detail to you, as he alone can do, the long years of effort by which he has raised this to the fourth place among the medical libraries of this country.

It is my simple duty to welcome you here, and to recount, briefly, the importance and the advantages of our work.

A medical library is peculiar in that it must also be a contemporary and a periodical library. The present is even more valuable to it than the past, although the records of the past are inestimable. It has been well said that the burning of the library of Alexandria set civilization back through all the centuries of the Middle Ages. So, were all records of medicine blotted out, the next generation of doctors would begin as children over again. What has been discovered has been recorded, and were that lost, humanity would be reduced to the rough medical practice of the savage. It is impossible to set a money value on medical science, and without the records of science, there would be no medical art. Were anatomy, physiology and pathology lost, we should be groping in the first footsteps of ignorance. Were the history of all diseases, recorded in our books, destroyed, we should be only children as observers. But to the younger doctors who listen to me it will appear that the present is all important. And if we were suddenly deprived of the knowledge acquired in the last fifty, twenty, or even ten years, what a change would come over medicine! Anesthesia, antisepsis and bacteriology are now the paramount factors of all our progress. And the peculiarity of this species of knowledge is that it is ephemeral; it lives but a day; it is not lost, but its seeds germinate in new discoveries the next day. What we know today may be obsolete tomorrow, simply because it is subject to daily investigation and daily modification.

This form of knowledge requires an ephemeral literature to record it. The monthly, the weekly periodical supply this knowledge. Hence the importance of a periodical library in medicine. More than five hundred such publications are taken here; read here; preserved here in files. This, then, constitutes a most valuable part of our library.

To allow the busy doctor and the student an opportunity to use this knowledge, it must be rendered accessible in commodious and quiet rooms, for reading, writing, excerpting. In our fine halls we can now offer the wisdom of the older authors, and the discoveries of almost every hospital and clinic and school in the world. Special subjects can be searched and exhausted; and the hurried doctor can drop in for half an hour and find the facts he is in search of, speedily and surely.

This is not all our function. A meeting house for physicians is also here provided; a medical centre, where professional intercourse will be aided by social features also.

I believe that the future influence of this Boston Medical Library on the doctors of New England will be beyond computation, in advancing science, softening prejudices and modifying opinions.

In 1874 six physicians met in the office of the late Dr. Henry I. Bowditch, and laid the foundation of this library association. Three of these gentlemen still serve us: Dr. F. I. Knight, as vice president; Dr. O. F. Wadsworth, as clerk; Dr. James R. Chadwick, as librarian. We may fittingly recall, also, that our assistant librarian, Dr. Edwin H. Brigham, is still in charge; having faithfully filled that office since 1875. Mrs. Collins, our cataloguer, has served us well for twenty-two years. Such permanence and reliability have been great helps in our progress. In 1877 an act of incorporation was obtained. Twelve of the fourteen original incorporators survive. We have lost three presidents by death: Dr. Oliver Wendell Holmes, presiding from 1875 to 1888; Dr. Hodges, presiding from 1888 to 1890; Dr. Minot, presiding from 1890 to 1896.

A quarter of a century has elapsed, and we have moved from Hamilton Place to Boylston Place, and thence, here. In this chaste and appropriate edifice we now are domiciled. That it is so well constructed we owe to the good taste of the architects, Messrs. Shaw & Hunnewell, aided by the suggestions and the oversight of our building committee, Drs. J. Collins Warren, J. R. Chadwick, Farrar C. Cobb. It is a noteworthy fact that we have completed our building for less than the estimated cost. This is unusual; and we owe it largely to the prudent management and practical knowledge of Dr. Farrar Cobb, whose experience in building a large hospital has well served him and us.

The young men in our ranks have pushed us on, and furnished that spur of enthusiasm which conservative age sometimes lacks. We owe also much of our financial success to the tact of our committee to solicit subscriptions, of which Dr. John Homans, 2d, is chairman. I consider that we have made a financial success, because we have collected by subscription about $73,000.

[1] Saturday, January 12, 1901.

We have paid out $125,000; and $15,000 will complete our building and furnishing; thus bringing the total cost up to rising $140,000. Sixty-seven thousand dollars are still due; but we have $25,000 to meet this, in land we own, unsold, leaving a balance of debt of $42,000. We have mortgaged this library, building and land, for $50,000.

Our younger members have generously guaranteed the interest on $25,000 for five years. And this leaves us a yearly burden of interest of about $1,000. We are not so badly off then. Fifty thousand dollars would clear us of debt.

But looking forward to the future we need an endowment to buy books. Many physicians have given us their libraries; others will do so as time goes on. But we need modern contemporary books. We ought to have on our shelves every modern treatise and textbook, in English, French or German, as soon as published; medical students and doctors alike need this. The interest of a modest sum would buy all the new books worth buying. We need a fund with a yearly income to enable us to receive students freely; to give them a room to themselves. We want students to come here as well as doctors, and we want to be able to give them good facilities for study.

Our hall for business meetings has been beautifully fitted up in memory of Dr. Richard Sprague, by his mother and by the Hon. C. F. Sprague. Mrs. Fifield, the widow of our late genial associate, has furnished a room, as a memorial. Holmes Hall speaks for itself. I need not describe its excellence. Would that some one might decorate and furnish the hall we occupy this evening. From the walls of Holmes Hall, from other rooms, look down upon us the portraits of many of our medical forefathers and teachers: The Warrens, Bigelows, Jacksons, Homans, Shattucks, Wymans, Bowditchs, Cabots, Putnams, Storer, Ellis, Buckingham, Holmes! How can I cease the enumeration? These were scholarly doctors. We need to continue this patrician *Gens*. Science enlightens, but does not wholly satisfy; the humanities in education soften manners, nor allow them to be harsh.

The moral effect produced on the patient and the community by the learned, as well as gentlemanly, physician, is great and wholesome. Let the doctor cultivate books, and let the influence of this library help him to do so.

It is now my privilege to introduce to you our librarian. If any one man were named who had collected and created our library, it is he. He is a bibliophile, who travels over Europe with a list of missing numbers always in his pockets. Persistent as the bee, he never comes home without honey.

ADDRESS

BY

JAMES R. CHADWICK, M.D.,
Librarian of the Boston Medical Library.

"*Horæ periunt et imputantur.*" "The hours perish and you must account for them." These words, taken from the sun-dial at Oxford University, seem to express the sentiment with which you give me your attention today, when I speak to you, fellow-associates, in the name of the governing body of this library. Hours have lengthened into days, days into years, and years have spanned the quarter of a century, since you laid upon our shoulders the burden of creating and building up a library to meet the wants of our profession in this community. Most of us have become silverites in the process of time and regard the ratio of sixteen to one as very moderate. A few are in position to follow the example of a friend of mine, who has discarded a brush and comb from his toilet set and claims that all he needs to do in the morning is to dust off the top of his head. A few, happily but few, of our early collaborators have fallen by the wayside and are no longer with us today to enjoy the full consummation of their efforts. I cannot mention them all; you know them — the impetuous, high-minded Bowditch, the beneficent Shattuck, the quiet, persistent Ellis, the sturdy Buckingham, the erudite Fifield, that dazzling genius Bigelow, and among the younger men, the scholarly Curtis, the wise Hooper, the wholehearted, witty Wigglesworth.

Last to be mentioned, but first in all your minds today, is he who lent us the prestige of his name at the inception of our undertaking — Oliver Wendell Holmes, our first president, litterateur, poet, wit, and for thirty-five years professor of anatomy at the Harvard Medical School. Our debt to him can never be paid, but we intend to keep it alive in our memory by dedicating to him our principal reading room, to be known through all time as Holmes Hall. His bust in bronze, a replica of that made by R. E. Brooks for the Boston Public Library, looks down upon us from over the mantlepiece at one end, his portrait by Billings at the other. We have many mementoes of him scattered through the hall; the latch of the house in which he was born; the earliest known portrait of him, a daguerreotype taken by Whipple & Hawes about 1845; his fist cast in bronze for me by the sculptor, T. H. Bartlett, with regard to which the latter tells an amusing and characteristic story. When Dr. Holmes was asked if he would hold a pen while the mould was being made, he said, "No," doubling up his fist like a prizefighter's. "Take it that way, which does not show the wrinkles of old age, does it?" His medical library of nearly 1,000 volumes, including many superb tomes of anatomical plates in which he took the keenest delight, will there find a suitable abiding place in accordance with his dying bequest in 1894.

In his poem "To the Portrait of a Lady" he says:

> "I love sweet features; I will own
> That I should like myself
> To see my portrait on a wall,
> Or bust upon a shelf;
> But Nature sometimes makes us up
> Of such sad odds and ends,
> It really might be quite as well
> Hushed up among one's friends."

His wish is gratified by us, his friends.

Happily, some of us, men of '75, survive to enjoy the pleasure of this moment, when we welcome you to the regal abode which your bounty has provided, in recognition of the library which our labors have brought together.

"The longest life" is said to be "a parcel of moments," so the largest library is but an aggregation of individual books. Exclusive of duplicates for home circulation, we have today upon our shelves about 33,000 volumes and 30,000 pamphlets; yet these figures give but a partial idea of our resources. To make this more clear I must bring to your minds the

change which time has brought about in the literature of medicine. Without dwelling upon the ponderous tomes in which was buried the medical lore of the early centuries after the discovery of printing, which your orator and president of twenty-two years ago dilated upon so learnedly and so wittily, I would ask you to come with me for a moment into the market place of Venice in the early part of the sixteenth century to scan a document, written in a legible hand, posted there and elsewhere in the city, for the perusal of those merchants who chose to pay a *gazzetta* for the privilege. You would find that it gave the news brought back to Venice by some one of its adventurous captains, who had strayed beyond the limits defined in his rude chart, and made another land discovery in the far West or the far South. "The arrival of the ship in the Adriatic, the contents of its cargo, the price of commodities abroad, together with some account of a newly discovered island, its wonderful people and marvellous products would form the staple of the news-sheet of the hour."

When in 1536 the Venetian possessions in the East were attacked by the Turks, the first regular monthly journal was established by the government to supply news from the fleet, and men were paid to read the particulars at the principal points of the city, but no sheets were issued except such as were sanctioned by the Doge and his council. The officials were so jealous of the printing press, however, that it was nearly fifty years after this time that the first printed newspaper was published in the city and dispersed every month into most parts of Christendom.

It is probably true, as claimed by the Germans, that their nation was the first to actually publish a printed newspaper, a certain *Relation*, which appeared in Strassburg, fifty-two numbers of which, dating from the year 1609, are preserved in Heidelberg. The *Frankfurt Journal* was not published until 1615; the first English paper, the *Weekly News*, in 1623; the first French journal in 1630.

Be that as it may, the now universal *Gazette* is seen to have come from the small coin originally paid for the perusal of its manuscript predecessor. From this modest beginning has developed the enormous mass of periodicals which characterize the literature of medicine and most other branches of science at the present day. In medicine the greater part of this change has taken place in the nineteenth century.

When six of us young men met on December 21, 1874, to discuss the possibility of founding this library, and when we actually did found it on August 20, 1875, we were fully cognizant of this change that was rapidly taking place in the character of medical literature; we knew that the era of theories and systems in medicine was being pulverized into nothingness by the accumulation of crude facts and that these facts were to be found chiefly in periodical literature. Periodicals were then increasing at so rapid a rate that few private individuals could afford to obtain, or even give, them shelf room.

We did not at that time foresee that this difficulty was to be increased a hundredfold, not merely by the multiplication of individual periodicals — great as that might become — but by the publication of a colossal index to all previous medical literature, including every article in every one of the numerous periodicals.

In 1879 the library of the Surgeon-General's Office in Washington, under the charge of an army surgeon, Dr. John S. Billings (whose presence here today is a fresh manifestation of his warm interest in our library), began the publication of an index catalogue of its collections, which comprised practically all medical literature up to that date. The first series of sixteen volumes, quarto, was completed in 1895; the new series comprising accessions since the publication of the first series has already reached the fifth volume.

Its value to medical scholars is inestimable, superseding, as it does, all the time-wasting labor that used to be expended in bibliographical research. By its aid we obtain a reference to every rare case that has been recorded since printing was discovered in A. D. 1450. But by indexing the articles and reports of cases in every periodical, past and present, obscure and famous, this catalogue has immensely extended the scope of medical research and created a demand for an array of books, and especially of periodicals, that is simply appalling.

I have dwelt at some length on this peculiarity of the medical literature of the present day that you might understand why it has been the constant aim of your librarian, during the past twenty-five years, to complete the files of all the important periodicals. His efforts have been attended with such success, despite the small funds at his disposal, that more than half of the volumes upon our shelves belong to that category. We are able to supply about seven-eighths of all the references to current literature demanded by our readers, even though they avail themselves of this great universal index.

It may pertinently be asked how our association, with practically no invested funds, has been able to achieve such results in the accumulation of books; for the table of curves suspended above me shows that in twenty-five years we have been able to outstrip many of the libraries which antedate us by many years in their foundation. Our library is already the fourth in size in the country, being exceeded only by that of the Surgeon-General's Office in Washington, that of the College of Physicians in Philadelphia, and that of the Academy of Medicine in New York.

I will tell you briefly. In the first place, we were fortunate enough to secure, at the onset, the custodianship of the libraries of all the societies pre-existing in the city. In the second place, most liberal contributions were made to us by many private individuals. In the third place, the completeness of our files of journals and transactions I attribute largely to the existence of the volume which I hold in my hand, my "want book," wherein, upon the left-hand page, is entered every periodical of which we have any part, while on the opposite page is entered every volume or number needed to complete the file of that particular journal. By invariably carrying this with me upon my travels in this country and Europe, I have been able gradually, at a trifling expenditure of money, to complete the files of all the leading periodicals of the world. I submit this to your special attention if you wish to know how to build up a medical library with practically no funds for the purchase of books.

So much for our accomplishment in the chief purpose for which we were brought into being. In some other ways we are making ourselves of use to the profession and to the community. For over twenty years we have been conducting a Directory for Nurses, which has been of immense value in putting,

at the shortest possible notice, the nurses of the State into communication with the physicians and their patients who wish to secure their services. Incidentally we have been able to raise the standard of nursing by putting a premium upon competence and training.

We have added to the amenities of professional life by supplying suitable halls for the meetings of the various medical societies and by hanging upon our walls the portraits of past worthies.

Within the past month we have received from Dr. Horatio R. Storer, of Newport, R. I., formerly of Boston, the gift of a most remarkable collection of medical medals, numbering 2,300 pieces. Only two other collections exist in the world at all commensurate with this, that of Dr. Joseph Brettaur, of Trieste, and that belonging to the library of the Surgeon-General's Office in Washington. Of the six other great collections that have been formed during the past two centuries, all have been scattered except that of Rueppelli, which was bequeathed to the Sankenbergische Gesellschaft of Frankfort. Considered either from its historic interest, its esthetic merits, or its pecuniary value, I consider this gift as the most noteworthy that this association has thus far received. It is to be known as the Storer Collection of Medical Medals in memory of Dr. D. Humphreys Storer, the father of the donor, and is to be in charge of a son of the donor, Dr. Malcolm Storer, an accomplished numismatist.

We have a collection of many thousand autograph letters of past and present medical writers and practitioners, only awaiting the appearance of a custodian with time and enthusiasm to classify them and thus make them available to students of history at its original sources.

To recapitulate briefly: We started in, twenty-five years ago, with the one purpose of supplying the needs of the medical profession in the way of literature properly catalogued and otherwise made available to all students. The gift of this spacious building from the profession of this city is the best evidence that we have achieved our purpose. Shall we rest contented with the laurels which we have won? I venture to hope not. I think that we acted wisely in limiting the expenditure of our energies and of our money to the one purpose of building up a library, so long as that was the one thing most needed in the city. Now that we have secured the library and the best equipped building in the country in which to store it, we may properly consider whether the time has not come to enlarge the scope of our functions by assuming the rôle of a society in addition to that of a library.

A rich merchant of Athens gave the use of his house and gardens on the outskirts of that city to several philosophic friends for the site of their reunions. There Plato instructed his numerous disciples. This place was called "Academy" from the name of the owner, Academus. Cicero gave the same name to his country place near the lake of Avernus and devoted it to the same purpose. Now that we have a similar spacious domicile, surrounded by gardens, which we owe to the munificence of the city, I would propose that we follow the example of our remote ancestors and invite our philosophic brethren to hold their reunions in our halls, not as guests merely, but as integral parts of our association, and that we assume the name as well as the obligations of an academy.

It is not merely on account of the archeological parallel, over which my fancy thus plays, that I make this proposition to extend so radically the sphere of our activity. I have watched for many years the careers of similar institutions in other cities and have come to believe that the conjunction of the double attributes of a library and a society much more than doubles the usefulness of the institution. The authority and prestige enjoyed in their respective cities by the Academy of Medicine in New York, and the College of Physicians in Philadelphia, have no analogue in Boston. I remember being greatly impressed with this lack of an authoritative body of medical men in our midst when I was reading many years ago of the spread of a yellow-fever epidemic. The question of a quarantine against it was under discussion in Philadelphia by the State and city authorities, who referred the whole subject to the College of Physicians, which appointed from its numbers a committee of experts whose report was accepted by the government as final and its recommendations carried out. I could not help thinking at the time that had our State and City Boards of Health, in which we take justifiable pride, needed guidance, or even the support of popular opinion, in such an emergency, they would not have known to what body of medical men they could appeal with the assurance that the public would recognize that body as authoritative. Apart from this important rôle, which we have a chance to fill, our new building will enable us to develop the social side of the physician's life. We may become to a fuller extent than heretofore the centre of all activity among the medical men of the State.

But this subject requires more study and deeper consideration than it can receive on such an occasion as this, and it needs moreover the enthusiasm of youth to bring it to a happy issue. It is time that we, men of '75, stepped down from our official positions and laid upon more stalwart shoulders the burden of accomplishing the latter part of our dream.

"And ye who fill the places we once filled,
And follow in the furrows we once tilled,
Young men whose generous hearts are beating high,
We who are old and are about to die,
Salute you; hail you; take your hands in ours,
And crown you with our welcome as with flowers!

"How beautiful is youth! how bright it gleams
With illusions, aspirations, dreams!
Book of Beginnings, story without end,
Each maid a heroine, and each man a friend!
Aladdin's Lamp and Fortunatus' Purse,
That holds the treasures of the Universe!
All possibilities are in its hands,
No danger daunts it, and no foe withstands;
In its sublime audacity of faith,
'Be thou removed!' it to the mountain saith,
And with audacious feet, secure and proud,
Ascends the ladder leaning on the cloud!"

PRESIDENT CHEEVER: We hope to make this building the permanent home of the Massachusetts Medical Society. The cohesive and conservative force of our parent organization is well represented in its president — the medico-legal pathologist, may I not say, of New England.

REMARKS

BY

F. W. DRAPER, M.D.,
President of the Massachusetts Medical Society.

IT is a congenial official duty, Mr. President, and an enviable personal honor, to respond to your call,

and, in the name of the Massachusetts Medical Society, to swell the chorus of congratulations which this occasion inspires. To one who has watched the evolution of this Medical Library from its beginning to its present moment, this jubilee is as appropriate as it is spontaneous. I recall the modest but hopeful way in which the library began its housekeeping in Hamilton Place. I remember in what an incredibly short time it burst its bounds, becoming so megalocheirous that all books in sight were gathered in; the result of this benevolent assimilation, this rapid expansion, was its removal to other and larger premises. How it has grown and prospered there, how it has faithfully fulfilled its mission, under somewhat trying conditions, while in that diverticulum of hidden dangers, that Bohemian midway pleasance, Boylston Place, you can all remember.

And now, following the westward example of every correct imperial course, it has made its second migration and has come here to what we may believe is its permanent home. And when we contemplate that home, its faultless architecture, its picturesque and dignified environment, its ample appointments, it is easy to join in expressions of gratification and to congratulate the library corporation upon this auspicious and most satisfactory achievement. Here the many thousand books which comprise this library have a fitting domicile, and one can almost hear them say, one to another, as they settle themselves contentedly in their permanent and harmonious places on the shelves, "Isn't this restful? Isn't this comfort?" Here the busy man in active practice can quickly find just the help he wants to take him over his clinical difficulties. Here the scholarly lover of good books can browse at his leisure in the well-tilled, overproductive fields of medical literature. Here the diligent seeker for facts finds in the files of current medical journals, gathered in this storehouse from all parts of the world, the latest record of research and observation. Here the ambitious undergraduate student of medicine, eager for knowledge, satisfies his longing.

And, then, there is another way in which this library meets the needs of medical men and appeals to their gratitude. I know of nothing quite so depressing in the experience of a sensitive physician as the absolutely heartless way in which his tried and trusted friends, the books in his medical library, are hustled and forced to the rear by new and strenuous candidates for favor. These older familiar guides and counsellors of his, whom he has loved and in whom he has confided, must be pushed aside to make room for the latest publication; senile obsolescence claims them as its victims while they are yet young. Something of the same sort is seen in the rapidly moving procession of new and revised editions of the standard works. You begin to get accustomed to Dr. Osler's classic volume when his second edition knocks at the door and seeks admission, and this has hardly settled in its place and become acquainted with its neighbors when the third edition is announced. And so it goes with all the writers whom we recognize as the leading authorities. The demand for new editions is good proof of the advance of medicine, but it requires an alert brain and a plethoric purse to do it justice. Thus it happens that most private libraries of medical books, belonging to physicians in middle life, contain many volumes too old to be usefully modern and not old enough to be valuable on that account. And it is here that the Medical Library in this building will help us; because, for the modest annual assessment, every member can have the benefit of the latest thing in medical literature, either in original works or in new editions. And this is a very obvious advantage.

The reasons why the Massachusetts Medical Society should take special interest in the Medical Library are plain. In all its century and more of organized life, our venerable but ever vigorous State medical fellowship has been the consistent patron of sound medical literature, the zealous advocate of the best in medical education, the cordial exponent of medical progress; and in all these relations it is in closest sympathy with the fundamental spirit and purpose of this library. I would remind you, too, that the membership of this institution is largely composed of Fellows of the Massachusetts Medical Society; that its entire administration has been in their hands, and that the successful development and nurture of it have been under their guidance and control. It is not surprising, then, that the Massachusetts Medical Society takes an interest in this consummation of an enterprise which you, sir, and your associates have accomplished. And it is entirely proper that it should add its laurel wreath of special appreciation as a tribute to the man whom Dr. Oliver Wendell Holmes once described as the "untiring, imperturbable, tenacious, irrepressible, all-subduing agitator, who neither rested nor let others rest until the success of the library project was assured." The description fits Dr. Chadwick today as accurately as it did in 1878.

I must not forget to allude to another and very intimate relationship which the library sustains towards the society, the relationship of landlord and tenant, continuing under this roof an association which has been mutually satisfactory for many years; and I am glad to have this opportunity to make public acknowledgment of the liberal and altogether acceptable manner in which the tenant's needs have been met. As time goes by, these large and attractive halls will be the scene of meetings and of conferences representing the best thought of the medical men of this community. More than that — here will be found the very centre and focus of our highest medical interests, the home of our medical sodality, where the rust of exclusiveness and reserve will be rubbed away by social contact with our fellows, and where we may cultivate mutual respect and courtesy, taking counsel together and standing together for the highest good of our profession.

These are some of the considerations, Mr. President, which not only inspire gratitude and congratulation, but awaken the most cordial hope that the library will have increasing prosperity through all its future; that it will be an important factor in promoting the progress of medicine in this city, there is not a shadow of doubt.

President Cheever: The professor of medicine of Johns Hopkins University is himself one of the best examples of the scientific progress of our profession. As a clear and forceful writer, as a sound, and not too progressive, practitioner, as a lucid expounder in the clinic, he is well recognized in our United States. He

has honored us by his presence and has promised to address us.

REMARKS[2]

BY

WILLIAM OSLER, M.D., LL.D, F.R.S.,
Professor of Medicine in the Johns Hopkins University.

THOSE of us from other cities who bring congratulations this evening can hardly escape the tinglings of envy when we see this noble treasure house; but in my own case the bitter waters of jealousy which rise in my soul are at once diverted by two strong sensations. In the first place I have a feeling of lively gratitude towards this library. In 1876 as a youngster interested in certain clinical subjects to which I could find no reference in our library at McGill, I came to Boston, and I here found what I wanted, and I found moreover a cordial welcome and many friends. It was a small matter I was seeking, but I wished to make it as complete as possible, and I have always felt that this library helped me to a good start. It has always been such a pleasure in recurring visits to the library to find Dr. Brigham in charge, with the same kindly interest in visitors that he showed a quarter of a century ago. But the feeling which absorbs all others is one of deep satisfaction that our friend, Dr. Chadwick, has at last seen fulfilled the desire of his eyes. To few is given the tenacity of will which enables a man to pursue a cherished purpose through a quarter of a century — "*Ohne Hast, aber ohne Rast*" ('tis his favorite quotation); to fewer still is the fruition granted. Too often the reaper is not the sower. Too often the fate of those who labor at some object for the public good is to see their work pass into other hands, and to have others get the credit for enterprises which they have initiated and made possible. It has not been so with our friend, and it intensifies a thousandfold the pleasure of this occasion to feel the fitness, in every way, of the felicitations which have been offered to him.

It is hard for me to speak of the value of libraries in terms which would not seem exaggerated. Books have been my delight these thirty years, and from them I have received incalculable benefits. To study the phenomena of disease without books is to sail an uncharted sea, while to study books without patients is not to go to sea at all. Only a maker of books can appreciate the labors of others at their true value. Those of us who have brought forth fat volumes should offer hecatombs at these shrines of Minerva Medica. What exsuccous, attenuated offspring they would have been but for the pabulum furnished through the placental circulation of a library. How often can it be said of us with truth, "*Das beste was er ist verdankt er Andern!*"

For the teacher and the worker a great library such as this is indispensable. They must know the world's best work and know it at once. They mint and make current coin the ore so widely scattered in journals, transactions and monographs. The splendid collections which now exist in five or six of our cities, and the unique opportunities of the Surgeon-General's Library have done much to give to American medicine its thoroughly eclectic character.

But when one considers the unending making of books, who does not sigh for the happy days of that thrice happy Sir William Browne whose pocket library sufficed for his life's needs; drawing from a Greek testament his divinity, from the aphorisms of Hippocrates his medicine and from an Elzevir Horace his good sense and vivacity. There should be in connection with every library a corps of instructors in the art of reading, who would, as a labor of love, teach the young idea how to read. An old writer says that there are four sorts of readers: "Sponges which attract all without distinguishing; Howre-glasses which receive and powre out as fast; Bagges which only retain the dregges of the spices and let the wine escape, and Sives which retaine the best onely." A man wastes a great many years before he reaches the 'sive' stage.

For the general practitioner a well-used library is one of the few correctives of the premature senility which is so apt to overtake him. Self-centred, self-taught, he leads a solitary life, and unless his everyday experience is controlled by careful reading or by the attrition of a medical society it soon ceases to be of the slightest value and becomes a mere accretion of isolated facts, without correlation. It is astonishing with how little reading a doctor can practise medicine, but it is not astonishing how badly he may do it. Not three months ago a physician living within an hour's ride of the Surgeon-General's Library brought his little girl, aged twelve, to me. The diagnosis of infantile myxedema required only half a glance. In placid contentment he had been practising twenty years in "Sleepy Hollow" and not even when his own flesh and blood was touched did he rouse from an apathy deep as Rip Van Winkle's sleep. In reply to questions: No, he had never seen anything in the journals about the thyroid gland; he had seen no pictures of cretinism or myxedema; in fact his mind was a blank on the whole subject. He had not been a reader, he said, but he was a practical man with very little time. I could not help thinking of John Bunyan's remarks on the elements of success in the practice of medicine. "Physicians," he says, "get neither name nor fame by the pricking of wheals or the picking out thistles, or by laying of plaisters to the scratch of a pin; every old woman can do this. But if they would have a name and a fame, if they will have it quickly, they must do some great and desperate cures. Let them fetch one to life that was dead, let them recover one to his wits that was mad, let them make one that was born blind to see, or let them give ripe wits to a fool — these are notable cures, and he that can do thus, if he doth thus first, he shall have the name and fame he deserves; he may lie abed till noon." Had my doctor friend been a reader he might have done a great and notable cure and even have given ripe wits to a fool! It is in utilizing the fresh knowledge of the journals that the young physician may attain quickly to the name and fame he desires.

There is a third class of men in the profession to whom books are dearer than to teachers or practitioners — a small, a silent band, but in reality the leaven of the whole lump. The profane call them bibliomaniacs, and in truth they are at times irresponsible and do not always know the difference between *meum* and *tuum*. In the presence of Dr. Billings or of Dr. Chadwick I dare not further characterize them. Loving books partly for their contents, partly for the sake of the authors, they not alone keep alive the sentiment of historical continuity in the profession, but they are the men who make possible such gatherings as the one

[2] Books and Men.

we are enjoying this evening. We need more men of their class, particularly in this country, where every one carries in his pocket the tape-measure of utility. Along two lines their work is valuable. By the historical method alone can many problems in medicine be approached profitably. For example, the student who dates his knowledge of tuberculosis from Koch may have a very correct, but he has a very incomplete, appreciation of the subject. Within a quarter of a century our libraries will have certain alcoves devoted to the historical consideration of the great diseases, which will give to the student that mental perspective which is so valuable an equipment in life. The past is a good nurse, as Lowell remarks, particularly for the weanlings of the fold.

> "'Tis man's worst deed
> To let the things that have been run to waste
> And in the unmeaning Present sink the Past."

But in a more excellent way these *laudatores temporis acti* render a royal service. For each one of us today, as in Plato's time, there is a higher as well as a lower education. The very marrow and fatness of books may not suffice to save a man from becoming a poor, mean-spirited devil, without a spark of fine professional feeling, and without a thought above the sordid issues of the day. The men I speak of keep alive in us an interest in the great men of the past and not alone in their works, which they cherish, but in their lives, which they emulate. They would remind us continually that in the records of no other profession is there to be found so large a number of men who have combined intellectual pre-eminence with nobility of character. This higher education so much needed today is not given in the schools, is not to be bought in the market place, but it has to be wrought out in each one of us for himself; it is the silent influence of character on character and in no way more potently than in the contemplation of the lives of the great and good of the past, in no way more than in "the touch divine of noble natures gone."

I should like to see in each library a select company of the Immortals set apart for special adoration. Each country might have its representatives in a sort of alcove of Fame, in which the great medical classics were gathered. Not necessarily books, more often the epoch-making contributions to be found in ephemeral journals. It is too early, perhaps, to make a selection of American medical classics, but it might be worth while to gather suffrages on the contributions which should go upon the Roll of Honor. I did a few years ago make out a list of those I thought the most worthy to 1850, and it has a certain interest for us this evening. The native modesty of the Boston physician is well known, but in certain circles there has always been associated with it a curious psychical phenomenon, a conviction of the utter worthlessness of the *status præsens* in New England, as compared with conditions existing elsewhere. There is a variety today of the Back Bay Brahmin who delights in cherishing the belief that medically things are everywhere better than in Boston, and who is always ready to predict "an Asiatic removal of candlesticks," to borrow a phrase from Cotton Mather. Strange indeed would it have been had not such a plastic profession as ours felt the influences which moulded New England into the intellectual centre of the New World. In reality, nowhere in the country has the profession been adorned more plentifully with men of culture and of character and, nappily, not voluminous writers or exploiters of the products of other men's brains — they would manage to get a full share on the Roll of Fame which I have suggested. To 1850, I have counted some twenty contributions of the first rank, contributions which for one reason or another deserve to be called American medical classics. New England takes ten. But in medicine the men she has given to the other parts of the country have been better than books. Men like Nathan R. Smith, Austin Flint, Willard Parker, Alonzo Clark, Elisha Bartlett, John C Dalton and others carried away from their New England homes a love of truth, a love of learning and above all a proper estimate of the personal character of the physician.

Dr. Johnson shrewdly remarked that ambition was usually proportionate to capacity, which is as true of a profession as it is of a man. What we have seen tonight reflects credit not less on your ambition than on your capacity. A library after all is a great catalyser, accelerating the nutrition and rate of progress in a profession, and I am sure you will find yourselves the better for the sacrifice you have made in securing this home for your books, this workshop for your members.

President Cheever: The librarian of the New York Public Library represents the largest collections of our land next to the Congressional Library. Fortunate for us and for medicine that he has given some of the best years of his life to our interests, and that in the Surgeon-General's Office and in the Army Museum and Library he has indexed the medical universe.

REMARKS

BY

J. S. BILLINGS, M.D., LL.D., D.C.L.,

Librarian of the New York Public Library.

No doubt we have all heard "platform figureheads" — of advanced years and much experience — commence their remarks on occasions like this by saying that one of the privileges of old age is the perspective, restrospective view which it gives of institutions, society and the world in general. I used to suppose that this was an excuse for, and explanation of, the attitude of sage and prophet assumed by the speaker, and that he enjoyed solid comfort in giving advice; but I am now beginning to appreciate how those old gentlemen really felt when they announced this important discovery. Most of them, I think, did not feel as wise as they looked, nor as certain and free from doubt as they did in their youth, but circumstance compelled them to speak, and this was a way to begin.

As I look back to the ceremonies of opening the then new building for this library in Boylston Place in 1878, I find that of the speakers on that occasion, I am the only one now present. President Eliot is still very much alive, although not here tonight; but Holmes, Ellis, Lyman, Smith, Henry I. Bowditch and Justin Winsor have passed away, and their biographies have been written. Fortunately, the results of their work remain and are enlarging, and one of these results we have before us tonight.

The medical prospect has changed somewhat within the last twenty-two years; there is a new literature, a new pathology, a new surgery, and new names for

some very old things, — Christian Science, for example, — but the old records have not lost all interest, and the special value of the library is that it contains both the old and the new. In his memorable address twenty-two years ago, Dr. Holmes rightly insisted that a library like this must exercise the largest hospitality, but this applies to gifts rather than to purchases. The funds for conducting a library, medical or other, are always insufficient, and the librarian, or library committee, must therefore exclude from the purchase lists many works which might be welcome additions if obtainable from other sources. The selection is sometimes difficult, and in making it, the work of other reference libraries in the vicinity, such as the public library, the university library, and some special libraries, must be considered. Even gifts must be scrutinized with reference to available space, and to their relative utility in other neighboring institutions. This library does not want a set of United States public documents, or of Massachusetts documents, although in each of these series there are a few things which it should secure. Curious things may be found in public documents. How many of you, I wonder, have ever heard of Herkimer Sternberg, and his great medical discovery, which is vaguely indicated in the following extract from Document No. 15 of the Assembly of the State of New York, dated January 15, 1859, being a report of the Committee on Medical Societies and Colleges, relative to the petition of Herkimer Sternberg for aid in publishing his manuscript of a proposed work. The committee reports "that they have had under their serious consideration the subject referred to them and have become satisfied if the prayer of the petitioner be granted, that the result of the scheme proposed by this Herkimer Sternberg, if successful, will be the annihilation of the medical profession, and thus the five or six thousand doctors of our State will be turned out upon the cold charities of an unfeeling world; that it will introduce the millenium several years before its proper advent in the regular order of business; that it will dislocate every joint in the system of the moral universe . . . and, therefore, the committee ask to be discharged from its further consideration."

In cities where there is no medical library, it is clearly the duty of the public library to provide some of the best medical books and periodicals for the use of the physicians of the city, as well as for the direct benefit of the public. It, is however, a matter of common experience that some lay readers are rather injured than benefited by reading medicine, and that it is best to restrict the use of certain classes of medical books. It simplifies the problems of the librarian of the public library when he knows that there is in the city a special medical library available for the use of physicians, and that he need only obtain those books which, if not exactly suitable for public use, are not calculated to do much harm. He will usually be glad to send to such a medical library the medical books of the eighteenth and most of the nineteenth century, old medical journals, miscellaneous medical pamphlets, theses, reports, etc., and to retain in the public library only those which have some interest in local history, or in other subjects besides medicine.

There are certain duties and responsibilities which rest upon a few large reference libraries which do not pertain to the great majority of city public libraries. For example, the average city library should collect and preserve all the reports of hospitals in its own city as a matter of local history, but it should not waste time or energy over the reports of hospitals in other cities, but should send those that come in either to a medical library or to one of the great reference libraries of the country like the Boston Public, the New York Public, or the Congressional Library. These great libraries must collect and preserve such reports as a part of their collections relating to charities — private and public — an important branch of sociology, but they are only useful in this way when the collections are very large and permit of comparisons of methods and results from a wide area and for considerable periods of time.

The field of medicine is very broad, and the special medical library might properly include not only general biology with its general subdivisions of morphology, physiology, psychology and anthropology, but also much of the literature of botany, zoölogy, chemistry, physics, municipal engineering, building and other applied sciences — and in fact the great medical libraries of London, Paris, Berlin, St. Petersburg and Washington do include many of these subjects. But this requires more space and money than most medical libraries can afford to give, and hence it is usually best to leave most of these subjects to other special libraries.

The department of first importance in a library like this is that which contains its files of periodicals, not only because they contain the original records from which textbooks and monographs are made up, but they represent the feelings, views and wants of the great mass of the profession, and are the great sources for the medical history of the nineteenth century. Medicine is now the most cosmopolitan and international of all the arts and professions, and this is largely due to its periodicals. Moreover, its periodical literature is now more accessible than that of any other profession because of the indexes upon which Dr. Holmes so much insisted. All this has been fully recognized by your librarian, and you are very rich in this class of literature. Thanks to the efforts of the medical profession of Boston (aided by those of some other parts of the country), Congress was induced to order the printing of the Index Catalogue of the Washington Collection which was under consideration twenty-two years ago, and which I then thought might make six volumes. This Index Catalogue is not yet finished, only twenty volumes having been published; but it can give considerable employment to the bibliographical student even now, and has probably added to the practical utility of this library, but perhaps not always to the perfect joy and content of its readers.

The fact that the physicians of Boston have another library besides this one to care for, as shown by their action with regard to the Index Catalogue, is one that I venture to remind you of because the needs of your National Medical Library are liable to be overlooked. Just now it is in urgent need of shelving for its additions, some of which are being stored in window sills or on the floor, which is bad for the books and for the readers.

Requests for funds to provide this shelving have been presented at the last two sessions of Congress, but received no attention. An estimate is before the present Congress for $9,000 to supply this shelving, and if the Massachusetts representatives and senators

hear from their medical constituents that this is a matter in which they are interested, there is no doubt that it will be done.

Your Washington Medical Library now contains 136,000 volumes and 230,000 pamphlets — decidedly the largest and best library of its kind in the world — and ought to be kept up to date in good shape.

When I tried to say something on the occasion of the opening of this library in the Boylston Place Building, I well remember that I was very much embarrassed and not a little afraid, and would have been very glad to have been merely a listener.

On the present occasion, while I am in trouble to find the right words in which to express my thoughts and feelings, I am very glad indeed to have the opportunity to congratulate you upon the result of the work of the Boston Medical Library Association during the last twenty-five years, and I do congratulate you most heartily and sincerely. The collection of books, of portraits, of medals, the building in its plan, structure and furnishings, are all things of which you have good right to be proud, and with which you may rest satisfied for several weeks to come.

As you all know, these results are largely due to the fact that one man having abundance of energy and public spirit, with much knowledge and an insatiable thirst for more, and with a fairly definite idea of what he wanted, has been working incessantly for the last quarter of a century towards this end. I congratulate you upon your wisdom in letting him thus work, and in helping him to carry out this plan. His power for good has not been limited to Boston, for by way of recreation he has devoted some of his time to stirring up and stimulating other librarians like myself, when he thought they needed it, or when he had some superfluous energy to dispose of, which was often. In this and other ways, he has given material and valuable assistance to other libraries, more than any of you are aware of, and it is not my personal affection for him, great as that is, but a sense of what is just and right, which leads me to say to you that, while the Boston Medical Library has been his special pet, for which no trouble was too great to take, and no sacrifice too great to make, all other medical libraries in this country are more or less indebted for their progress and prosperity to your librarian, Dr. James R. Chadwick.

President Cheever: The genial professor of therapeutics from Philadelphia will now address us. He is also a professor of nervous diseases, but he will omit that branch on this occasion. As representing the oldest medical centre in America, and still among the most modern, I take especial pleasure in introducing him to you.

REMARKS

BY

H. C. WOOD, M.D., LL.D.,

College of Physicians of Philadelphia; Professor of Nervous Diseases and Therapeutics, University of Pennsylvania.

Mr. President and Gentlemen who have assisted in the creation of the Boston Medical Library. — It is with a high sense of the honor conferred upon me that I bring greetings and congratulations in this, the opening of the twentieth century, to you, the fruit of whose labors is seen in the substantial edifice and the loaded bookshelves which surround us; greetings and congratulations from the College of Physicians of Philadelphia.

In doing this I desire to express most warmly my appreciation of the great work which has been done largely through the efforts of a few men among you, and in a comparatively brief period. It may well be questioned whether so rapidly a successful effort has been equalled upon the American Continent, and I trust that it will be understood that what I have to say in regard to the institution which I represent is said in no spirit of egotism, but simply as the effort of age, perhaps senile and garrulous, to read lessons to the young through its own experience.

The College of Physicians of Philadelphia was born January 2, 1787, amidst surroundings most primitive, and has grown with the growth of American civilization. That the founders of the college had very clear ideas as to the necessity of a medical library for the increase of medical knowledge, and for the perfection of medical units, is shown by the fact that during the first year of its existence the college discussed the subject, and a few weeks later, namely, on March 3, 1788, by the formal acceptance of the gift from Dr. John Morgan of 24 volumes, by the approval of a regular plan for a library, and by the appropriation of fifty pounds — Colonial — for the purchase of books, laid the foundation of that collection of medical books which is today the most valuable of its kind in the United States, save only the one in Washington belonging to the Federal Government. In the library of the college at Philadelphia there are at present 61,359, or including duplicates, 65,499 volumes, besides unbound pamphlets; there is also an especial fund of $50,000 for the purchase of new books.

It has seemed to me, in thinking over what I know of the profession in Boston, that possibly it might be well for the association of physicians which has been successful in the creation of the library about us to widen the scope of its operations, and thereby do great good and indirectly assist the library itself. So far as can be seen, if the founders of the College of Physicians had made the creation of the library their sole object, the library would have soon perished as one born out of due time. It has been the cohesive influence of aims other than those purely scholastic which has bound together successive generations of medical practitioners in Philadelphia so firmly as to make possible the gathering together of medical books; an object which was perhaps secondary in the minds of the founders, and besides which in their acts is clearly foreshadowed a threefold intent.

Plainly first among the results which it was hoped to attain was by fostering intercourse amongst fellows of the college to increase that personal friendship and amity which restrains far more powerfully tendencies to professional jealousy and undue rivalry than can any written law of ethics or any inculcation of precepts of professional conduct even during the educational period of life; the result has been that there are few members of the college who do not value the friendship and esteem of their fellows as their choicest possessions, and that the relations between members of the profession in Philadelphia are among the most perfect in the world.

The second object, for the attainment of which the

college was seemingly organized, was for the stimulation in its members of professional zeal in study and in doing what they could for the enlargement of the boundaries of medical knowledge. Even if time allowed, it would be scarcely becoming in me to show how successful the years have been in this respect, nor yet is it needful: the history of medicine in Philadelphia must be sufficiently known to you to recognize that in no other centre in the United States have there been more men of national or international fame, or more success either in actually increasing knowledge or in preparing it as brain food for the rank and file of the profession.

The third intent, which was early manifested in the acts of the college, was to afford a body of physicians, the conjoint local reputation of whose members would be sufficient to give overwhelming weight to any deliberate expression of opinion made by the assembly upon matters medical in which the general public was concerned.

A few months after the foundation of the library, namely, in April, 1789, the influence of the college was first brought to bear upon the public authorities. The old records show that at the time there was a widespread epidemic of influenza in Philadelphia; that the President of the United States was to visit the city on his way from Mt. Vernon to New York, where he was to be inaugurated; and that among other ceremonies a general illumination was proposed; but that on the representation of the college that the late night exposure in the month of April would undoubtedly increase the number of victims of the prevailing disease, the proposed illumination was abandoned. The action of the college and its results may after all have been matters of no great importance, but they were drifting straws, showing the set of the current of public opinion; a current which later in the same year led the Legislature of Pennsylvania to formally apply to the college for assistance in the emendation of the State laws for the prevention of the introduction of infectious diseases.

To make further citations of similar instances of correlation between the College of Physicians and the governmental authorities of the State or of the city would require simply a going over the records of the history of the college, but I have been sternly warned not to overpass ten minutes of time, so I forbear; only calling attention to the fact that the College of Physicians has frequently taken part in governmental procedures, and that the degree of attentiveness of the governmental ear to its voice has usually been a fair measure of the wisdom and the honesty of the governmental brain. As politics in the modern sense of the word has grown among us to be more and more of a special business, so has the governmental ear been dulled; as city or State governments have risen or ebbed in the standard of their purity, so have the admonitions of the college been listened to or neglected; and usually has the community reaped the reward or paid the penalty for such action, since in most cases the decisions of the college have been correct.

Such, gentlemen, is the brief lesson which I would read to you from the long and successful history of the College of Physicians of Philadelphia; led by it I venture to urge that for the continuing success of your library, for the internal benefit of the profession in Boston, for the advancement of medical knowledge within your bounds, for the general good of the community in which you dwell, the association should broaden its scope, so that it should become not simply a library association but a veritable collegium, whose fellows pass through life hand in hand, in all fidelity inciting each other to good works.

May I further add that the history of the Philadelphia College indicates that in such broadening certain matters must be attended to. It seems to be primarily essential that all school fellowships and affiliations be laid aside in the membership. Alumni associations are well, but they have here no place. The graduate of Harvard must for the time being forget his Alma Mater in a wider brotherhood, so that whether a man be a Boston graduate, or come from the far-off University of Tokyo, or from the school of Göttingen, he shall be equally available for membership in the association and for honors in its body politic. On the other hand, almost equally essential is it that no attempt be made to interfere with what may be considered the normal political aggregation of physicians in the United States, namely, the county medical societies, growing upward to the State societies, and then to the general association in the United States. In the county medical societies every legalized physician, who is willing to be honest and upright in his profession, should have the right to take part, but in the proposed organization the standard of membership should be higher; so that membership in the association should be looked upon as an honor, because it stands not only for high professional purity and ethicality, but also for high professional zeal and culture. It is given to but few to be professional leaders, but many can be honest medical gentlemen, highly cultured students, and thoroughly conscientious physicians; of such and of such only should be the membership in the suggested College of Physicians of Boston.

PRESIDENT CHEEVER: It is a good omen for us that a doctor of medicine is even a temporary ruler of Harvard University. Medicine and our Medical Library are well represented in the corporation. But in the acting president we have a conspicuous example of sanitary, professional and executive ability.

REMARKS

BY

HENRY P. WALCOTT, M.D.,

Acting President of Harvard University.

THE opening of a library devoted to the general purposes of literature, history and art would compel the representative of a great teaching body to say something about the appeal which such collections make to the cultivated and intelligent members of the community. We cannot, however, say that this collection of books will ever appeal to us in the higher sense in which the masters of literature have swayed their worlds.

You shall find no author here who has made a figment of his imagination as real as an actual personage of history.

The diseases of the human race, and I may add, too, those of the domesticated animals, have an interest that needs no play of the imagination and not even the graces of style. The description, however, must

have scientific accuracy, and that implies competent authority.

We read in vain the matchless pages of Thucydides to discover the real nature of the plague at Athens; the great historian could not adequately describe a disease which he not only saw, but from

books as have become of historical interest only.

The explanation of this seeming lack of care on the part of the university for her Medical School, in which she takes a just pride, is undoubtedly to be found in the fact that the resources of this library have been most freely given to the teachers and students of the school. The authorities of the university may well consider whether some equitable arrangement may not be possible for giving to the library an equivalent for the valuable and necessary assistance so freely and generously bestowed.

ment of his imagination as real as an actual personage of history.

The diseases of the human race, and I may add, too, those of the domesticated animals, have an interest that needs no play of the imagination and not even the graces of style. The description, however, must

have scientific accuracy, and that implies competent authority.

We read in vain the matchless pages of Thucydides to discover the real nature of the plague at Athens; the great historian could not adequately describe a disease which he not only saw, but from which he had himself suffered. Our pious ancestors resolved that "good learning should not perish from among us," and so founded the schools at Cambridge. The first substantial help was given by John Harvard, but little less precious than his bequest in money was the legacy of his books. It is well, then, that we should here cherish books, and it may be interesting to consider for a moment how Harvard College has used its libraries.

In my own college days the librarians were little more than watch dogs of the collections under their charge. Beyond the volumes of Reis's Cyclopædia, the *North American Review* and some of the English quarterlies, students were rarely allowed access to the actual presence of the books; twice a week we were allowed to take out books for use in our rooms.

The result was that the faithful officers turned over to their successors the unused and well preserved contents of the shelves. A generation has passed away, and I can now read in the latest report of the college librarian the following statement:

"The number of books but continues to increase at a fairly steady rate. Borrowing has doubtless been encouraged by the large number of attractive books, both old and new, that are constantly kept on open shelves in the delivery room, where every one who comes into the library is tempted to look them over."

The whole number of students in Cambridge is 3,151; number taking books, 2,488. The collection is open both daytime and evening through the week and also on the afternoon of Sunday. The university library is credited with the possession of 548,000 books; of these, however, only 379,000 are deposited in the general collection in Grove Hall. The rest are in the various departments and laboratory libraries; the Law School has 50,000 volumes; the Museum of Zoölogy, 34,000; the Divinity School, 30,000; the Astronomical Observatory, 9,000; the Gray Herbarium, 7,500, and last, and in this case least, the Medical School, is said to have 2,240.

Beyond this system of department libraries there is another and more extensive system of laboratory and classroom libraries, twenty-four in number, varying in size from the library of history, political economy and sociology of 4,500 volumes, down to the Preachers' Library in Wadsworth House of less than 100 volumes.

In this enumeration, the striking fact is the absolute poverty of the Medical Library as compared with the collection with which a comparison may be justly sought — the zoölogical library built up under the fostering care of its great and generous curator; a working library only, which is annually turning back into the great receptacle in Grove Hall such books as have become of historical interest only.

The explanation of this seeming lack of care on the part of the university for her Medical School, in which she takes a just pride, is undoubtedly to be found in the fact that the resources of this library have been most freely given to the teachers and students of the school. The authorities of the university may well consider whether some equitable arrangement may not be possible for giving to the library an equivalent for the valuable and necessary assistance so freely and generously bestowed.

President Cheever: We had hoped to have with us tonight the Holmes of Philadelphia, himself both a lover and an author of books, a valued contributor to medical and to general literature, a master of style in prose and in verse. I ask Dr. Chadwick to read a letter from Dr. S. Weir Mitchell.

LETTER

FROM

S. WEIR MITCHELL, M.D., LL.D.

Philadelphia, December 29, 1900.

Nothing, my dear Chadwick, except engagements, not to be broken, keeps me from being among those who in person congratulate the profession on the opening of your new library. To you more than to any other I send my gratulations, for to this end you have given costly days out of a busy life.

I see as I grow old, or may I say older, how few are the young medical men whose tastes are scholarly, and who, like Holmes and our own lamented Da Costa, are familiar with the fathers and find pleasure in the old books — the quaint books, the sense and the vagaries of the past. Without a great library few can afford these intellectual playgrounds, or, indeed, acquire the material for such indulgence.

May your new building and growing wealth of books tempt many into paths where some of us have found unlooked for treasuries of interest and even of practical value; for indeed the dying century did not invent common sense, and genius is of every age.

I often remember with regret the great waste of time in my younger days when there were no great libraries, and when John Billings had not indexed the medical thought of all the centuries. The enormous labor then involved in any mere literary research as to facts no one can imagine today. A great library of medicine is truly a labor-saving machine, and over your library and over its new home you should rejoice because a great library, well managed, practically lengthens life by saving time.

My thin thread of New England blood seems to be tingling with friendly pride as I reflect on what the profession has here accomplished. I send you my greeting from the city I love best to that I love next best, and wish you all, and the newly instituted library, long, useful and honored days.

As I pause to assure you how truly I am yours I am conscious that I really have more and better things to say; but as like as not others will have said them, and I leave therefore to the eloquence of suggestive imagination all the fine things which I am tempted to say and will not.

Believe me, my dear Chadwick, always and in all ways,

Your friend,

S. Weir Mitchell.

NOTE ON THE TREATMENT OF EPIDERMOID CANCER BY THE RÖNTGEN RAYS.

BY FRANCIS H. WILLIAMS, M.D., BOSTON.

RECENTLY I have had the opportunity in this JOURNAL of directing attention to the value of the x-rays in the treatment of ous and since that time further experience has confirmed my belief in it as a therapeutic agent in lupus vulgaris.

I desire now to state my conviction that the x-rays are of value in the treatment of certain forms of cancer. Their usefulness in relieving pain in cancerous growths was demonstrated in Germany some time since, and in the *Philadelphia Medical Journal* of December 8 and 15, 1900, Drs. Wallace Johnson and Walter H. Merrill have presented an excellent article on the x-rays in the treatment of cancer. My experience differs from theirs in some respect , but before referring to it I will consider one or two points relating to face cancer. It is well known that this form of cancer may yield to treatment with caustics and as they insist on the importance of causing a burn, it would seem quite possible that the good results they have obtained might have been due to the caustic action which they state it is essential to excite. They produce a mild inflammation, gradually increasing its severity till there is a burn of such depth that it would require six weeks to heal on a healthy skin.

My experience at the Boston City Hospital indicates that we have either in the x-rays themselves or in some other form of radiation from an excited Crookes' tube a valuable therapeutic agent in epithelioma and that the beneficent action of the x-rays can be brought about without causing a burn. The patients to which I chiefly refer entered the Boston City Hospital in the service of Dr. H. L. Burrell, who at my suggestion had a small piece of the growth taken out and submitted to Dr. Mallory; the latter reported that the growths were epidermoid carcinoma. Then Dr. Burrell most kindly had the patients transferred to my care. I have convinced myself that without causing any pain and without the delay or inconvenience to the patient of an x-ray burn we can accomplish excellent results with this new method of treatment. Foul and nearly unbearable odors cease, the discharge becomes less and the growth steadily diminishes in size.

The earlier this treatment is undertaken the better. It is not improbable that we shall find its curative action limited to superficial growths, though as a means of relieving the painful features of the disease in other forms it may be of some use.

The delay in seeking medical advice for the treatment of a new growth in its earliest stages has been caused in many cases by the dread of the knife, but there is nothing to be feared in the use of the x-rays if they are properly applied; that is to say if the apparatus, especially the Crookes' tube, is suitable, the distance of the patient and the duration of the exposure are properly chosen and other necessary precautions are taken.

Later on I shall present in more detail the results of the use of the x-rays in the treatment of cancer.

Medical Progress.

REPORT ON THE DISEASES OF CHILDREN.

BY T. M. ROTCH, M.D., BOSTON.

KOPLIK'S SIGN IN MEASLES.

WIDOWITCH [1] has studied the diagnostic value of Koplik's spots in a recent epidemic of measles at Gratz. He examined 158 cases. The spots were found in 140 of the cases, 88.6%, and were absent in 18, 11.4%. Other prodromal symptoms which confirm the diagnosis were found in 115 of the cases in which the spots were present. In the other 25 cases it was the only prodromal symptom present.

He concludes, therefore, that Koplik's sign is not pathognomonic since it was wanting in one-tenth of the cases, and most often was associated with other prodromal symptoms. He also found it 10 times in 135 cases of rubella, in 1 case of follicular angina, and in another of stridulous laryngitis. He thinks this occurrence in other diseases diminishes its value. [Even if not pathognomonic, a sign which is found in nearly 90% of the cases of measles, not infrequently without the presence of other prodromal symptoms, is certainly of the greatest diagnostic value. Too much reliance, moreover, cannot be placed on the observation of the spots in 10 cases of rubella, for the diagnosis between measles and rubella is notoriously difficult.]

Rolly [2] found the sign from four days to six hours before the eruption in 24 of 78 cases of measles. In 11 cases in which it was not observed the examination was not made until from twenty-four hours before the eruption to four days after, too late a period from which to form definite conclusions as to the presence or absence of the sign at an earlier stage of the disease. He never found the spots in scarlatina, bronchitis, diphtheria, aphthous stomatitis, or numerous other diseases.

Hirsh [3] concludes that Koplik's sign is always present in the beginning of measles. The spots are present from twelve hours to five days before the cutaneous outbreak. The number of these spots bears no relation to the severity of the attack. They are found in no other condition of health or disease.

Maroney [4] studied 140 cases of measles, and concludes that Koplik's spots are an absolutely pathognomonic sign of measles from which a positive diagnosis can be made at an early stage of the disease. In the great majority of cases they appear before the skin eruption, and in almost one-half the cases before coryza or conjunctivitis. Their recognition allows early isolation, and provides a means of limiting epidemics in hospitals and institutions.

Ross [5] concludes from the study of 15 cases that Koplik's sign is most valuable, rendering an early diagnosis possible before the appearance of the exanthem. It is of assistance in differentiating true measles from rötheln, erythema and scarlet fever, and also from diseases which simulate measles in their early stages, such as influenza and simple colds.

THE PRESENCE OF DIPHTHERIA BACILLI IN THE MOUTHS OF HEALTHY INDIVIDUALS.

Kober[6] has made an extended study in Flügge's laboratory regarding the frequency with which diphtheria bacilli are observed in healthy throats. He examined 128 persons who had been exposed to diphtheria and 600 who had not knowingly been exposed. The diagnosis of the presence of Klebs-Löffler bacilli was made by cultures upon serum and microscopical examination after six hours, by Neisser's double stain with cultures from nine to eighteen hours old, by the acidity test and by inoculation of guinea pigs. He found diphtheria bacilli in healthy throats much less often than had previous observers. In his series they were found in only 8% of the persons exposed to diphtheria, and in only 2½% of those not exposed to diphtheria. It was found on further inquiry that two-thirds of those who were thought not to have been exposed had really been exposed directly or indirectly to the focus of the disease. Excluding these, the proportion of unexposed individuals having the bacilli in their throats is reduced to .83 of 1%. The organisms found in the throats of those known to have been exposed were all virulent; two-thirds of those found in the non-exposed were non-virulent.

THYMUS DULNESS.

Blumen Reich[7] studied the thymus dulness on more than 100 children, some ante mortem and some post mortem. He found that post-mortem examinations were as satisfactory as ante-mortem. He used light percussion and percussed for the absolute, and not the relative dulness. According to him the thymus gives rise to an area of dulness which is irregularly triangular in outline, the base being made by the line connecting the two sternoclavicular articulations, the blunt apex situated at the level of the second rib or slightly below it, and the sides a little beyond the edges of the sternum. The larger half of the triangle of dulness usually falls to the left side. When the limit of dulness given above varies by one or more centimetres or obscures the pulmonary resonance between the upper line of cardiac dulness and the lower lateral limit of thymus dulness, an enlargement of the thymus gland is indicated. The thymus dulness is present until the end of the fifth year, after which it is inconstant. He found that swollen lymph nodes in the anterior mediastinum do not cause dulness, but that cheesy lymph nodes do.

PRIMARY SPLENOMEGALY.

Boviard[8] under this title, or endothelial hyperplasia of the spleen, describes 2 cases of his own in children, and 4 others collected from literature. His 2 cases were sisters. In one the disease began at three years, and death occurred at sixteen years after splenectomy; in the other it began at two years, and the child was alive four years later. He gives the symptomatology, based on the observation of his own and of the other cases, as follows: Slow progressive enlargement of the spleen beginning in childhood; enlargement of the liver secondary to that of the spleen, which may be considerable but not reaching the extent of the splenic affection; simple anemia, the only changes observed in the blood being those associated with any chronic enlargement of the spleen; softening of the gums with oozing of blood and repeated epistaxis; in some cases cutaneous hemorrhage and icterus; finally symptoms referable to the mechanical effect of the splenic enlargement — pain in the abdomen, disturbance of the functions of the stomach and bowels, dyspnea, dysuria, and cramps in the legs. The disease is not fatal *per se*. From the history of the patients and collected observations he concludes that the enlargement of the liver is secondary to that of the spleen.

The autopsy of his fatal case showed that the organs were essentially normal except the spleen, liver and abdominal lymph nodes. The characteristic feature of the pathological process in the spleen, liver and lymph nodes was the multiplication of endothelial cells associated in the cases of both spleen and liver with a great increase in the connective tissue of the organ. He concludes that the process is not a new growth, but an endothelial hyperplasia of the spleen, and that it may be associated with like changes in the retroperitoneal and mesenteric lymph nodes and in the connective tissue of the liver. He thinks that it is a definite, distinct disease and can be differentiated from any previously described, including splenic anemia. At present, however, the only sufficient distinction of the type of the disease is the pathology. That is altogether different from anything else to be found in medical literature.

SCLEROSIS OF THE PANCREAS FOLLOWING CHRONIC GASTRO-ENTERITIS.

Arraga and Vinas[9] having noticed the frequency of changes in the pancreas in children dying of chronic gastro-enteritis, they studied the pancreas carefully in 10 cases from two to eight years old. They found it to be hard, more or less diminished in volume, and the seat of a chronic angiopancreatitis, as demonstrated by microscopic examination. The inflammatory process apparently spread from the intestine through Wirsung's duct to the pancreas. The acini suffered less than the ducts. They maintain that the pancreatic lesion is of the first importance in the symptomatology, prognosis and treatment of gastro-enteritis.

EXTRACT OF THE SUPRARENAL CAPSULES IN THE TREATMENT OF RHACHITIS.

Stoeltzner[10] studied the action of suprarenal extract in the treatment of rhachitis in Heubner's clinic. He arrived at the following conclusions:

(1) Suprarenal extract influences very favorably the general condition, the vasomotor excitability, and the craniotabes. All these symptoms are often considerably relieved in one or two weeks.

(2) Children soon begin to sit up, to walk and to run. The softness of the thoracic bones disappears very rapidly, and the delayed teeth appear.

(3) The epiphyseal enlargements and the deformities of the head, thorax and extremities are but little influenced.

(4) Spasm of the glottis is seldom much helped.

(5) The amelioration of the symptoms is most marked during the first week of treatment; later, it is less rapid.

[9] Arch. de méd. des enfants, vol. iii, No. 7.
[10] Jahrb. f. Kinderheilk., 1900, Bd. i, S. 73, 199.

(6) Improvement ceases or there is a return of the symptoms if treatment is interrupted. Improvement begins again with the renewal of treatment.

(7) Even in cases complicated by syphilis, enteritis or bronchitis, this treatment helps the rhachitis considerably.

THE ELIMINATION IN INFANTS IN THE URINE OF SUGARS INTRODUCED SUBCUTANEOUSLY OR BY THE DIGESTIVE TRACT.

Nobécourt[11] calls attention to the fact that while the conditions which regulate absorption, assimilation and elimination of various forms of sugar have been thoroughly studied in the adult, very little work of the kind has been done in infants. He has therefore undertaken an investigation of the subject with reference to the first three years of life. He arrives at the following conclusions:

(1) The intestinal mucous membrane of the infant has a powerful converting power as regards lactose. It transforms considerable quantities of lactose introduced into the intestines with the milk, and is capable of transforming single doses much larger than are ever contained in an ordinary breast feeding. In general this power is more marked in the young infant than in the adult, but there are numerous exceptions.

(2) The intestinal mucosa of the infant possesses also the power of inverting saccharose. It seems as active in one case as in the other, if the dilution is the same. Glycosuria was never observed in the normal infant with lactose or saccharose. In some rhachitics alimentary glycosuria was produced with glucose. At this age the organism has a more marked action upon glucose than in adult life. This action does not seem to be limited to the liver but extends to all the tissues.

CONTRIBUTIONS TO THE STUDY OF THE TOXIC ACTION OF MILK OF TUBERCULAR ANIMALS.

Jemma[12] presented a preliminary report of some experiments he had performed upon rabbits to determine what action a tubercular milk sterilized at 100° C. would have when administered daily as a food. Small rabbits several days old were used. One set of animals was fed on sterilized milk to which had been added tubercle bacilli which had previously been subjected to a temperature of 100° C. for fifteen minutes; a second set of animals was fed on sterilized milk without the addition of tubercle bacilli; a third set was allowed to nurse from their mothers. Jemma states that the rabbits which had been fed on the milk containing the dead bacilli gained very little in weight and after fifteen or twenty days some of them died in a state of advanced cachexia; others continued cachectic and died of a marked degree of marasmus, even though the absorption of the bacilli had been suspended. The autopsies showed a mild enteritis, characterized by a redness of the intestinal mucous membrane and a fatty degeneration of the liver. The two control sets of rabbits neither lost in weight nor appeared at all disturbed. The conclusion is drawn that the sterilization of a tubercular milk at 100° C. cannot counteract the injurious action of the toxins, and that for infants the only milk which should be used should be that from cows which have been proved free from tuberculosis by the tuberculin test.

[11] Rev. mens. des mal. de l'enfance, 1900, vol. xviii, p. 161.

[12] Paper read before the Congrès contra la Tuberculose, held at Naples in April, 1900.

THE EXANTHEMATIC FORM OF TYPHOID FEVER IN CHILDHOOD.

Weill and Lesieur[13] describe at considerable length the chief peculiarities of this form of typhoid fever, which are the early appearance and generalization of the eruption together with the mildness or absence of digestive symptoms. In most cases there are no symptoms, objective or subjective, attributable to the digestive tract. The liver is not enlarged, the spleen not at all, or but little increased in size. In some cases, however, the digestive symptoms are more marked, but even in the severe cases they diminish or disappear when the eruption becomes generalized. The prognosis is good, recovery being the rule within fifteen or twenty days. The fever rarely continues longer than three weeks. Relapses sometimes occur, but are insignificant.

No complications were seen in this form of typhoid. Fifty-eight of these cases were seen among 280 cases of typhoid fever during six years; 22 were mild, 15 of medium severity, 12 grave, and 9 had relapses. This form is easily distinguishable from the ordinary form of typhoid in children, both mild and severe. The abundance of the rose spots is a favorable prognostic sign only if it coincides with the absence or diminution of digestive disturbances. It has the same significance even in cases which appear to be grave.

Reports of Societies.

NEW YORK NEUROLOGICAL SOCIETY.

STATED meeting, December 4, 1900, FREDERICK PETERSON, M.D., president.

THE TERMINAL CONDITION IN A CASE OF DIPLEGIA.

DR. WILLIAM M. LESZYNSKY presented a man, twenty-one years of age, in whom the chief feature of interest was a trembling of the hands, which had existed as long as he could remember. Nothing was known of his early history except that he had always been nervous. His mother had died of cancer of the uterus. The trembling had always been more marked on the left side, and his condition was apparently growing steadily worse. On careful examination no disturbance of sensibility could be detected. There was excellent muscular development on the left side and a spinal curvature, probably arising from the use of one side more than the other. There were no signs of atrophy. There was some asymmetry of the cranium. There was no disturbance of vision, but concentric contraction of the visual field. There was no nystagmus, and the pupils and fundi were normal. There was a positive tremor when at rest, and a more active tremor on motion. He holds the left arm in extension, but close scrutiny shows that all of the rigidity is in the extensors. The elbow jerk was elicited only on the right side. Both knee jerks were exaggerated. Ankle clonus had been demonstrated on both sides, though much more marked on the left. Dr. Leszynsky said that this man had probably recovered from a paralysis that he had had at one time, and was now suffering from a terminal condition of infan-

[13] Rev. mens. des mal. de l'enfance, vol. xviii, No. 526.

tile palsy. Undoubtedly there was a good deal of functional disturbance added to the organic trouble.

DR. M. ALLEN STARR thought the case was an athetosis on the left side, and that probably the same lesion, to a minor degree, was present on the opposite side. It was apparently a post-diplegic condition.

DR. B. ONUF called attention to the lordosis and the unusual muscular development of the deltoids.

DR. E. D. FISHER also looked upon the case as one of cerebral diplegia, most marked on the left side, and with the athetoid movements often seen in such cases. This extreme muscular development seemed to him not at all uncommon in this class of cases. He would like to know concerning the electrical reactions.

DR. B. SACHS said that there could be no doubt that the left side was the centre of disturbance, and it was also probable that a part of the tremor was functional. The condition of the muscles in the scapular region seemed to him fully accounted for by the spinal curvature present.

DR. F. PETERSON agreed with the diagnosis of post-paralytic athetoid form of movement. Where the paralysis was small he thought these finer movements were more apt to be present.

DR. LESZYNSKY regarded the remarks of Dr. Sachs a sufficient answer to those of Dr. Onuf. He had not yet tested the electrical reactions. It seemed to him that this man could be benefited if properly trained. Hypnotism had been suggested, and it seemed to him worthy of trial. The method used for ataxics would probably prove beneficial; it had just been commenced.

REPORT OF TWO CASES OF SPINAL TUMOR WITH OPERATION AND REMOVAL.

DR. M. ALLEN STARR said that five years ago he had been able to collect 145 cases of spinal tumor, in 22 of which operation had been undertaken. In the cases forming the subject of the present paper the symptom pain had been very prominent, and this together with the symptoms of pressure on the cord had allowed of the diagnosis being made.

CASE I. Mrs. E. W., thirty-five years of age, had been in good health previous to March, 1899, at which time she had begun to suffer from paroxysms of pain near the heart at night. They were not brought on by exertion, but were much increased by touching a region to the left of the nipple. From September, 1899, to May, 1900, she had been treated by many physicians for angina pectoris, hysteria and other disorders. Nitroglycerin had always intensified the pain. On May 10th, Dr. Theodore Janeway had examined her, and found her in an extremely nervous condition and suffering from constant pain. The left knee jerk was exaggerated. Over the left side of the dorsal spine was extreme sensitiveness from the first to the eighth dorsal spine, and over the corresponding intercostal nerves at the angles of the ribs. There was no affection of the arms and the internal organs were normal.

When examined by Dr. Starr on October 26th, she was suffering much from pain at the level of the fifth and sixth intercostal nerves, much more marked on the left side. There was very marked tenderness over the dorsal region from the first to the seventh dorsal spine. A condition of partial anesthesia was found on the trunk and total anesthesia in the legs. Her legs were quite powerless, but there was no atrophy of the muscles. Ankle clonus was present on both sides, and both limbs were cold, blue and edematous. She had recently been unable to control the sphincters. Dr. Janeway had made a diagnosis of tumor of the spinal cord at the fifth dorsal segment.

On October 22d she was operated upon by Dr. McCosh at the Presbyterian Hospital. On dividing the dura an extremely edematous state of the pia was observed, with one white plaque lying upon it. The cord was smaller and whiter than normal, and was not pulsating. No tumor was found. Three days later the wound was enlarged upward and the dura found to pulsate freely at the upper level, but not lower down. A tumor, 1½ inches in length, lay upon the cord. It was oval, had a distinct capsule, and was removed *en masse* without difficulty. Subsequent examination showed it to be a fibroma. The cord had been reduced to about one-half its diameter beneath the tumor. No attempt was made by nature to heal the first operation wound, and in spite of great care an extensive bed sore developed over the hip. In the second week after operation the constricted feeling became less marked. The operation wound healed very slowly. In the fourth week after the operation she had constant fever, probably because of the extensive bed sores. The spinal incision healed about this time, but she died a few days later.

The autopsy showed a softened condition of the cord opposite the exit of the second dorsal nerve from the dura, and the fifth and fourth dorsal nerves could be traced into this area. Owing to the rudimentary condition of the spine of the third cervical vertebra, an error of one vertebra had been made in the count at the time of operation. The case seemed to emphasize the fact that there should be no delay in operating for spinal tumor after the diagnosis had been reached. In this case the delay had arisen from an effort to try the effect of antisyphilitic treatment, the husband being known to be syphilitic. Bed sores had developed before the operation, and had continued to extend in spite of it, and had eventually caused death from sepsis. Gumma of the spinal cord is quite rare, only 26 cases having been found in a series of 400 cases. The tumor had been found about 2 inches higher than had been anticipated. Reed's table had been used as a guide at the first operation, but according to Bruns, the operation should be done two segments above the upper limit of pain. This advice was nearer the truth in the present case. The level of the pain was about 8 inches lower than the level of the tumor; hence in operating for spinal tumor the level of the cord should be exposed at least 4 inches higher than the level of the spinal nerve in which pain is found.

CASE II. Mrs. K., forty-six years of age, had been in good health until May, 1900, when after a slight injury she had been delivered of a dead child. Soon afterward she had begun to suffer pain over the left hip, and this pain had extended down to the left knee. It had caused insomnia and progressive loss of health. In September she had noted numbness of the left foot.

On October 16th, on admission to the Presbyterian Hospital, she was pale and feeble, and seemed to be suffering from paroxysms of pain over the left trochanter and that side of the sacrum. There was a drop foot due to paralysis of the peronei and anterior tibial muscles. The bladder required catheterization, and the rectum had to be emptied by enema. There was an area of anesthesia down the back of the left thigh and leg, and a smaller area was found on the right side. Under mixed treatment the paralysis extended and the pain became more severe. An area of tenderness to pressure was found over the second, third and fourth lumbar vertebræ, and pressure here aggravated the pain in the hip. It seemed probable from these facts that there was a tumor pressing on the cauda equina, and extending as high as the level of the exit of the second lumbar nerve. The functions of the sacral nerves and last lumbar nerve were evidently affected on the left side. A diagnosis of a caudal lesion was reached because of the level of the pain.

On November 15th Dr. McCosh removed the spines and arches of the second, third and fourth lumbar vertebræ. Dissection showed a tumor involving both the soft and hard tissues of this region. The spines and arches had been eroded by the tumor, which subsequently proved to be an endothelioma. This tumor had invaded the spinal canal and produced pressure on the dura.

The patient was in a critical condition for two days after operation, but since then had improved rapidly, and had had no pain since the operation. A considerable degree of atrophy had developed in both peronei. The wound had healed perfectly and there was no evidence of recurrence. It was reasonable to hope for recovery unless there should be speedy recurrence.

Out of 145 cases of spinal tumor that he had collected, the history had been fairly clear in 122. In 76 cases an operation should have been feasible, and according to the pathological report in 75% the tumors could have been removed.

DR. A. J. MCCOSH said that he had found spinal surgery much more satisfactory than brain surgery; certainly the localization of the lesions had been more satisfactory. It was difficult to say, however, that a lesion is situated at any one segment of the spinal cord, but as a portion of the cord equal to three or four vertebræ must be exposed a slight error in localization is not of great importance. He had had recently a case presenting symptoms almost exactly like those of the first case reported in the paper. The line of anesthesia had been almost the same, but there had been no paralysis of the arms. The autopsy showed a crushing injury of the cord between the fourth and sixth cervical vertebræ. The ordinary rules laid down had indicated a lesion much lower down, and he had in this way been misled at the operation. He had not found laminectomy a very serious operation as a rule, most of the patients having exhibited comparatively little shock; hence, one should not hesitate in advising the operation when the diagnosis was sufficiently clear. He agreed thoroughly with what Dr. Starr had said about the inadvisability of delaying the operation for weeks in order to give antisyphilitic treatment a trial. He had met with a number of cases in which he believed the fatal result was attributable to such delay. When bed-sores were already present the case was practically hopeless, the patient almost invariably dying from sepsis. It is well to remember that tumors of the cord are usually found higher up than the estimated level. By beginning above and working downward, it seemed to him that the healing process would be favored. He was not of the opinion that there was any good ground for believing that the operation of laminectomy so weakens the spine as to lead to disability. Mention was made of one of his cases in which a man was engaged at an occupation requiring the frequent lifting of heavy weights, yet he had felt no inconvenience as a result of the operation upon his spinal column.

DR. PEARCE BAILEY reported this case of a man, forty-one years of age, who has been treated for some time previously for a variety of troubles. When seen in May he had stated that about fifteen months previously he had begun to have intense pain on the inner side of the left thigh. There had been an interval of a few months in which this pain had almost subsided. There was slight atrophy in the left leg; the left knee jerk was absent; there was very slight anesthesia. The case seemed to be one of tumor of the cauda equina. Dr. McCosh had operated upon him on the 22d of May. He had removed the last dorsal and the first and second lumbar vertebræ, and had exposed what had looked at first like a blood clot, but microscopical examination had proved this to be a round-cell sarcoma. Although it was probable that all of this sarcoma had not been removed, the man had done extremely well all these months; was free from pain and had resumed his occupation.

DR. SACHS coincided with those who had advised against delaying in these cases in order to try specific treatment. He was thoroughly in favor of operating just as soon as the diagnosis had been established with reasonable clearness. It was a great mistake in his opinion to look upon operation as a *dernier ressort*. Gumma of the cord was quite rare, and even in these cases very little had been accomplished by the administration of the iodides; hence, such treatment might very well be neglected. In one of his cases in which the operation had been done quite early the man had been restored promptly to health. In another case he had not been allowed to operate early, and the recovery had been far from satisfactory. It seemed to him that a little too much importance was attached to the mere matter of localization; the important question was in regard to the nature of the morbid process and whether or not a tumor is present. In Pott's disease the sensory disturbances were sometimes quite as marked as where there was a tumor of the cord. Pain was the important symptom, but this was applicable more particularly to dorsal rather than to ventral tumors. He was not prepared to speak regarding the relative frequency of these two forms of tumor. He was of the opinion that a very extensive laminectomy could be done without causing notable disability or deformity. Early operation, he felt sure, would make spinal surgery much more satisfactory than brain surgery.

DR. THEODORE C. JANEWAY said that he regretted very much that in his cases the diagnosis of spinal tumor had not been made sooner. There had been pain a year previously, but the pain had disappeared for a considerable time, and when he had first seen her she had been so extremely nervous that the question of hysteria had been seriously considered at first. The case had progressed very rapidly during the part of the summer in which he had not seen her.

AN ANALYSIS OF THE SYMPTOMS OBSERVED IN CASES OF TUBERCULOUS MENINGITIS AT THE BABIES' HOSPITAL.

DR. C. A. HERTER read a paper with this title. There were 24 cases of tuberculous meningitis, and in 15 of these there were autopsies. In these 15 cases, 6 were at the age of eight months; 7 were one year old or under. In 9 cases of tuberculous meningitis without autopsy, 6 were five months old. These figures showed that tuberculous meningitis was not so rare in the first year of life as had been supposed by some writers. Nineteen of the cases had run their course in less than one month. The fontanelle had been markedly distended in 7 of the 24 cases, and in 3 there had been a marked excess of fluid found at autopsy. In 1 case the fontanelle had been depressed — a case sick for four or five months. In 6 cases there had been a delay in the closure of the fontanelle. Vomiting had been noted in 19 of the 24 cases, and had been the first symptom in 14 cases. In 5 in which there was no vomiting the autopsy showed nothing different from the cases that had presented vomiting. In 11 cases there had been marked constipation. In cases coming to autopsy there had also been tuberculous lesions in the intestine. In several of the cases there were tuberculous ulcers of the colon, and yet

constipation instead of diarrhea had been present. The pupils were unequal in 12 of the 24 cases, and dilated in the others. The pupils were contracted in only 2 cases. Nystagmus was observed in 4 cases, and strabismus in 10 cases. In the cases showing strabismus there were marked lesions at the base and in the interpeduncular space. There were general convulsions in 50%. There was no case which did not present either rigidity or convulsions. In cases without meningitis, but with tubercles in the brain, convulsions were not so common. Paralysis was noted in 10 of the 24 cases of tuberculous meningitis, and was monoplegic in a number. The variability of these palsies was a rather notable feature. In the cases without meningitis, but with tubercles in the brain, no palsies or paralyses were noted. The *tâche cérébrale* was noted in 7 cases and flushing of the face in 10 cases. All the cases of tuberculous meningitis with autopsy had presented stupor or coma, or more or less irregularity of respiration, while these had not been observed in any of the cases with tubercles, but without meningitis. Hyperesthesia had been noted in only 1 case, and in only 1 had there been a well-developed cephalic cry. Retraction of the abdomen had been noted to a greater or less degree in 15 of the cases of tuberculous meningitis, but not at all in the other cases. The fever had not been high in the uncomplicated cases, and the pulse had shown nothing distinctive. In the cases without meningitis marked opisthotonos and convulsions had been the rule, and early vomiting had been much less frequent than where meningitis was present. Only 2 or 3 of the cases had presented solitary tubercles. In all of the autopsy cases the cerebral tuberculosis had been clearly secondary. The intestine was the seat of tuberculous lesions in 11 of the 13 cases in which the intestine was examined. The knee jerks were increased in a large proportion of cases, and absent in only 2. An interesting feature was that at times the knee jerks would be alternately exaggerated and absent.

DR. LESZYNSKY said that he had made some observations in children under three years with regard to the knee jerk, and had noted that in the early stages the knee jerks had seemed to be absent, but as soon as the pressure symptoms appeared the knee jerks became exaggerated and remained so until death.

DR. SACHS said that the diagnosis of tuberculous meningitis was usually delayed by the general practitioner because he overlooked, as a rule, the cranial nerve symptoms so commonly found quite early in these cases, and waited for some of the more common and typical symptoms. He would like to know whether examination of the fundus and lumbar puncture had been of any diagnostic aid.

DR. HERTER replied that lumbar puncture had been practised in a few instances, and in 2 or 3 tubercle bacilli had been found. The examination of the fundus had been undertaken in so few cases that no deductions could be made. None of the cases diagnosticated as tuberculous meningitis had recovered.

DR. SACHS said that in a series of cases of sporadic meningitis lumbar puncture had been made, and the diplococcus had been found in almost every instance. He had been surprised also at the large number of recoveries in these cases of sporadic meningitis in which the diplococcus had been found. Their clinical course had been greatly at variance with the older descriptions of cerebrospinal meningitis. The onset had been very violent, the fever lasting often a week or more, and then recovery was rapid.

DR. HERTER said that in the cases he had seen there had been a much more violent onset than in tuberculous meningitis.

Recent Literature.

Diseases of the Eye. By EDWARD NETTLESHIP, F.R.C.S., Ophthalmic Surgeon at St. Thomas's Hospital, London; Surgeon to the Royal London Ophthalmic Hospital, etc. New (sixth) American from the sixth English edition, thoroughly revised by WILLIAM CAMPBELL POSEY, M.D. With a Supplement on the Detection of Color Blindness by WILLIAM THOMSON, M.D., Professor of Ophthalmology in the Jefferson Medical College, Philadelphia. Just ready. Pp. 562, with 192 illustrations, and 5 colored plates. Philadelphia and New York: Lea Brothers & Co. 1900.

Mr. Spicer so well accomplished a revision of the sixth edition three years ago that it has been thought well to offer still another, which, however, comes to us from Dr. William C. Posey. In this recent volume attention has been given especially to the methods of examination and the therapeutic measures employed by practitioners in this country, and although the subject matter, as a whole, shows but little change, all that is new regarding the bacteriological origin of certain diseases has been introduced. Dr. Thomson has thoroughly revised his section relating to the visual tests for railroad employés, while in an appendix will be found a concise statement of the laws governing the visual tests for admission into the public services of the United States, which have been obtained from the authorities at Washington, and are for the first time presented in a collected form. The methods employed in examining the eyes of school children in different American cities have been added.

The Treatment of Fractures. By W. L. ESTES, A.M., M.D., Director and Physician, and Surgeon in Chief of St. Luke's Hospital, South Bethlehem, Pa. Pp. 220. Illustrated. International Journal of Surgery Co. 1900.

This book discusses the treatment of fractures. The "mechanics" of fractures are considered only when necessary to elucidate or suggest proper treatment. The writer holds that reduction of deformity and fixation is not the whole treatment of a fracture, but that the entire condition, local and general, and every indication must be borne in mind. His data for this volume, he states, have been derived from a review of modern authorities and a personal experience of fifteen years of hospital work.

The book is indexed, but is not divided into numbered chapters, and contains no "table of contents." The classification made is an anatomical one. After a few pages devoted to treatment in general, the main part of the book is devoted to the consideration of specific fractures, arranged in the following order: Cranium, face, trunk, upper extremity, lower extremity. The concluding pages deal with compound and complicated fractures.

The book contains many practical suggestions and many truths. It is a presentation of personal ideas and convictions rather than a discussion of the subject from a broad standpoint.

The author has had apparently a large experience in the treatment of railway and machinery accidents. His description of his methods in dealing with these severe and often extremely complicated injuries, not only the emergency or "first-aid" handling of the patient, but also the full or permanent treatment of the case, is full of excellent ideas. His results as published show that of 67 cases of complicated fractures of the extremities of all degrees of severity, 54 recovered with useful limbs; in 9 patients the limb was saved but with its function not fully restored; 2 subsequently required amputation and 1 died. This is an excellent record, and a demonstration of a method which justly claims careful consideration. The aseptic and operative technique as described is good, but in some details differs from that employed by many surgeons.

In regard to the treatment of simple fractures, also, the writer's experience and personal study of the conditions encountered have developed points relating to mechanical indications for and varieties of apparatus, bandages, etc., which are always of interest, at least, if not of value. He is apparently one who has done his own thinking, and not followed passively and blindly the routine road.

Kurzgefasstes Lehrbuch der Kinderheilkunde für Aerzte und Studirende. Von DR. CARL SEITZ, a. o. Universitätsprofessor und Vorstand der Kinderpoliklinik am Reisingerianum in München. Pp. viii, 499. Second enlarged and entirely revised edition. Berlin: S. Karger. 1901.

In the preface to the first edition the author stated that his object was to describe the various diseases of children as completely as possible, and yet as briefly as practicable. He has certainly accomplished this object most admirably. The book is not a small one, as the title would suggest, but a good-sized volume. In this second edition it has been thoroughly revised and in many places entirely rewritten. We know of no book on the diseases of children which contains more condensed, accurate and up-to-date information than the one under consideration.

The book is divided into two parts; the first dealing with general considerations, the second with special diseases.

In the first part the first chapter treats of the anatomical and physiological peculiarities of children, and is remarkably good. The second deals with the care and feeding of infants. The general remarks regarding the digestion and feeding of infants are excellent; the methods of feeding, however, are not up to the best standard of this country. The third chapter, describing the methods of physical examination in children, is admirable, and one of the best we have seen on this subject. The next chapter, dealing with the treatment of sick children, is not as good as the others. In fact, throughout the book the weak point is treatment.

The chapters of the second part, in which special diseases are described, are so uniformly good that it is difficult to discriminate. The classification of disease is, on the whole, very satisfactory, although we hardly see why myxedema, Graves's disease, and the various anemias should be grouped among the "general diseases." The strongest point in this part of the book is the differential diagnosis. In diagnosis the greatest stress is laid, as it should be, on physical examination and not on symptomatology. The modern methods of laboratory diagnosis are all mentioned and their importance and usefulness emphasized. The sections dealing with physical diagnosis are excellent, and worthy of careful study.

The work is certainly a most admirable one, and well worthy of a place among the most used books of both the student and the practitioner.

Ringworm in the Light of Recent Research. By MALCOLM MORRIS. With 22 microphotographs and 1 colored plate. London, Paris and Melbourne: Cassell & Co. 1900.

This work of Morris's has only just reached us, but it is not too late for a word of recognition of its merits. Mr. Morris has made investigations of his own on the subject of ringworm, and has reached the conclusion that there can be no doubt of the plurality of the ringworm fungi, although he is by no means prepared to accept all the subdivisions and varieties proposed by Sabourand and others. His opinion is that, "There are at least two, probably three, possibly more, distinct species of fungi which produce the disease in different cases." The work gives an admirable epitome of our present knowledge of ringworm and of the recent advances that have been made in its investigation. The microphotographs are of very great value. There are some interesting chapters on diagnosis and treatment, and on the prevention of the affection in schools.

A Compend of Diseases of the Skin. By JAY F. SCHAMBERG, A.B., M.D. Second edition, revised and enlarged, with 105 illustrations. Philadelphia: P. Blakiston's Son & Co. 1900.

This second edition of Schamberg's "Quiz Compend of Diseases of the Skin" has just appeared, revised and enlarged, with the addition of a number of new photographs. Its merits are not beneath those of the very numerous similar publications that are constantly appearing.

A Practical Treatise on Fractures and Dislocations. By LEWIS A. STIMSON, B.A., M.D., LL.D. (Yale), Professor of Surgery in Cornell University Medical College, New York; Surgeon to the New York and Hudson Street Hospitals; Consulting Surgeon to Bellevue, St. John's and Christ's Hospitals; Corresponding Member of the Société de Chirurgie of Paris. Third edition, revised and enlarged. With 336 illustrations and 32 plates in monotint. New York and Philadelphia: Lea Brothers & Co. 1900.

This is the third edition of this book. In the second edition the book was largely rewritten and important additions have been made to this last edition. The part which deals with fractures, especially in the classification and arrangement of the chapters on fractures of the skull, has been essentially rewritten. The chapter on the advance of our knowledge on the traumatic hematomyelia is, in this edition, well presented and forms an important addition to our knowledge of the prognosis and treatment of injuries of the spinal cord.

The book is well illustrated, a number of new plates

having been added, principally of skiagrams. There are still many ancient and respected cuts of fractures and forms of splints which do not add essentially to the value of the book.

Dr. Stimson's work on fractures and dislocations is now an authority. It is a book which can be turned to by any one who wishes to make a thorough research in any given subject. It is judiciously written and well presents the known knowledge of this important subject. The experience gained in the House of Relief (Hudson Street Hospital) "where traumatic cases are so numerous as to include all the ordinary forms of injury, and most of those which are rare" will, we hope, allow the writer to replace some, at least, of the cuts which are only time-honored and are not of any great value.

A Manual of Operative Surgery. By LEWIS A. STIMSON, B.A., M.D., Surgeon to the New York and Hudson Street Hospitals; Consulting Surgeon to Bellevue, St. John's and Christ's Hospitals; Professor of Surgery in Cornell University; Corresponding Member of the Société de Chirurgie, Paris, and JOHN ROGERS, JR., B.A., M.D., Surgeon of Gouverneur Hospital, New York; Instructor in Surgery, Cornell University. Fourth and revised edition, with 293 illustrations. Philadelphia: Lea Brothers & Co. 1900.

This octavo volume of 582 pages has now reached its fourth edition. It is an excellent, condensed handbook of operative surgery. The descriptions of operations are simple and definite, governed by the author's experience, and, while the larger books give more lengthy descriptions, yet in many instances the descriptions are all sufficient to one who is somewhat familiar with operative surgery. Except for completeness we see no particular advantage in including operations of the eye and ear in a book of this description. However. the book is undoubtedly constructed for the use of general practitioners, who may be called upon to do any and all operations. The book is fairly well illustrated, and, as the author says, many of the ancient cuts have been eliminated.

Surgery, its Theory and Practice. By WILLIAM JOHNSON WALSHAM, F.R.C.S. (Eng.), M.B. and C. M. (Aberd.), Surgeon and Lecturer on Surgery, St. Bartholomew's Hospital; Member of Court of Examiners, Royal College of Surgeons of England; Consulting Surgeon to the Metropolitan Hospital, to the Hospital for Hip Disease, Sevenoaks, and to the Cottage Hospital, Bromley; late Surgeon in Charge of the Orthopedic Department and Lecturer on Anatomy, St. Bartholomew's Hospital; Examiner in Anatomy to the Conjoint Board of the Royal College of Physicians and Royal College of Surgeons. With 483 illustrations, including 16 skiagram plates. Seventh edition. Philadelphia: P. Blakiston's Son & Co. 1900.

This is the seventh edition of this book. The author has rewritten many of the sections and much of the material which had become obsolete has been omitted. Many skiagrams have been introduced and evidently great care has been taken to bring the book up to date. As a condensed presentation of the subject of surgery, it is only fairly satisfactory, many of the methods and much of the apparatus being antiquated.

THE BOSTON
Medical and Surgical Journal

THURSDAY, JANUARY 17, 1901

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE BOSTON MEDICAL LIBRARY.

THE formal opening of the new building of the Boston Medical Library which took place Saturday evening, January 12th, was an event the full significance of which we are as yet not fully able to appreciate. Boston has for many years struggled to maintain a creditable library in a building which had become wholly inadequate and in a situation whose character had so changed as to justify its being not inaptly described by one of the speakers of the evening as a "diverticulum of hidden dangers, a Bohemian midway pleasance." To be suddenly transferred from this unfortunate position to its present location on one of the city's most attractive streets, commanding a view of exceptional beauty, is a transformation which the most sanguine believer in the fitness of things could contemplate only with satisfaction tempered by surprise. How this was accomplished was told in detail at the exercises attending the opening of the new building, the full report of which is given in other columns of this issue. We will only emphasize here the good fortune of the building committee in being able to command the devoted services of a medical colleague, Dr. Farrar Cobb, with large experience in the details of the construction of buildings for medical institutions; he, in great measure, wrought the miracle of providing an architectural product at less than estimated cost.

As was to be expected, the attendance at these exercises was large and representative; it is perhaps more worthy of comment that the various addresses and remarks made by the chosen speakers were most admirably suited to the occasion, and did not once lapse into the commonplace. They were throughout dignified, at times humorous, but never tiresome. Dr. Wood, of Philadelphia, was the only absentee, but we have fortunately not thereby lost his address. The exercises were held in the large upper hall, as yet unfinished; its bare walls and girders were a mute but eloquent appeal to the assembled audience to provide at no distant time for the proper adornment of this

important room, for which the modest sum of $5,000 is required.

In striking contrast to this commodious but as yet incomplete hall is the main reading room, which is to be known as Holmes Hall, in honor of the steadfast friend and first president of the library. No doubt many deserve the credit for this room, but to whomsoever credit is due, there can be no question that it is a success from every point of view. Dr. Holmes is evidently the presiding genius, for his portrait looks down from one end and his bust from the other, while everywhere are further reminders of Boston's literary doctor — many of them due to the fostering foresight of Dr. Chadwick. It was hard to believe that this room had not been in use for years, so assiduously had its shelves been filled with books, and its various decorations completed. The recently acquired collection of medical medals presented by Dr. Storer will when finally in place afford a unique object of interest to Holmes Hall.

The skilful arrangement of the smaller rooms to be used for various purposes connected with the library — among them Sprague Hall, for the smaller meetings of medical societies — reflects equal credit upon the designers of the building. It is, in fact, hard to see how the most ambitious among us could demand a more elaborate and complete receptacle for our books and medical treasures of all sorts, or a more satisfactory literary workshop. Even Dr. Billings, who knows whereof he speaks, comforted us with the assurance that we "may rest satisfied for several weeks to come."

True as all this is, and justifiable as are self-congratulations at this time on what has been so successfully accomplished, the fact must not for a moment be lost sight of that much more remains to be done; that with new privileges come new responsibilities of a very definite sort. The library must be supported as never before; it must continually have new books, and widen its scope of usefulness in every possible direction. To this end a renewed interest must be taken in its affairs by every one, whether remotely or intimately connected with it, an interest which, no doubt, the new building will do much to stimulate.

A suggestion in this line was made both by Dr. Wood, speaking for the College of Physicians of Philadelphia, and by Dr. Chadwick, Librarian of the Boston Library. Both of these gentlemen urged the desirability of widening the scope of the library with the view of establishing ultimately an association of physicians, whose voice would have weight in other matters than those pertaining merely to books. This means a very distinct expansion over the organization which at present exists. Dr. Chadwick urged that the library henceforth invite men working in allied fields to form a part of the proposed larger association, which then might properly assume the name and the obligations of an academy. The library should thereby become the real centre of the medical activity of the entire State, or we might go still further and say, of New England. It is clear, as Dr. Chadwick said, that the subject is a large one, demanding careful consideration and active enthusiasm before such a general plan may become an accomplished fact. In the meantime it behooves us to recognize our new responsibilities and by all ways in our power to enhance the usefulness of the library merely as a library, and also by broadening the present organization lay at least the foundation of an institution which shall represent the widest medical interests. We are confident that such a consummation is both possible and desirable.

THE RESPONSIBILITY OF THE DOCTOR.

We have recently been edified by somewhat heated accounts in certain of our daily contemporaries regarding the alleged unjustifiable action of several physicians, who refused attendance upon a dying man. Beyond the sensational newspaper reports we know nothing of the actual facts of the case. A man died from suffocation due apparently to the lodgment of food in the larynx; several physicians were summoned in haste; it is claimed that they declined to go; the man was beyond relief when a doctor finally arrived on the scene, but we are led to suppose that his life might have been saved had skilled assistance been immediately obtainable. One of the physicians summoned is said to have expressed his willingness to respond to the call, if he were paid a small fee in advance.

Whatever the merits of this particular case may have been, there is clearly involved in the incident a principle of importance. It is generally assumed by the laity that a physician is bound to respond to a call for his services whenever made, and however inconvenient to himself, regardless of a possible fee. It goes without saying that physicians usually live up to this assumption, hence the popular clamor when for any reason they assert their prerogatives as free men, and decline their services. It is a notorious fact, and one which every individual's experience demonstrates, that the business standards which regulate payment for services rendered are peculiarly inoperative in the case of physicians. Some people, not all by any means, have an extraordinarily lax conscience when the doctor presents his bill. Is it to be wondered at, therefore, that even doctors occasionally turn, and request a preliminary guarantee of the honesty of their patients, and particularly when those patients are wholly unknown to them? This, as a general practice, we should deprecate; it is not at all likely, nor is it desirable, that the lawyer's retainer, for example, be adopted as a routine practice by the physician, but it is equally evident that a doctor is quite within his right when he makes such a demand, and especially is this true of the emergency case. It is altogether desirable that people at large should be made to feel that a physician's services have a money value, which

must under all conditions be respected. How far we are from this state of things is evident from the popular clamor which an incident like the foregoing excites. The physician's side of the question is quite forgotten in sympathy for the unfortunate man who died.

It is a gratification to quote the following reasonable remarks from the editorial columns of a lay journal. "They (doctors) are almost completely at the mercy of the public and the public shows them little mercy in return for their ofttimes merciful attention. At any hour of the day or night the doctor is expected to be ready to answer rush calls for medical attendance, and is not surprised when, in return for his services, he gets nothing more substantial than promises, the majority of which are never fulfilled. Is it to be wondered at that, after meeting with hundreds of such experiences, he decides to refuse emergency calls from strangers unless he makes certain of at least a small recompense? To such an extent is this disregard of obligation to medical men carried that it is surprising that most of them are so generous with their time and services."

MEDICAL NOTES.

Smallpox. — On January 9th 267 cases of smallpox were reported in the State of Kansas. The disease is of a more severe type than existed last winter. In the city of Galveston, Texas, there are a number of cases of smallpox. The disease was probably brought to Galveston by the influx of a large number of country negroes. Every bale of cotton, also, that comes from the Senegambia district is liable to convey the malady and several cases have been traced to this source. General vaccination is being strongly urged. The disease is not of a virulent type.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, January 16, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 143, scarlatina 39, measles 62, typhoid fever 16.

Boston Mortality Statistics. — The number of deaths reported to the Board of Health for the week ending January 12th was 233 as against 240 the corresponding week last year, showing a decrease of 7 deaths, and making the death rate for the week 21.67. The deaths from consumption were 29, pneumonia 35, whooping cough 1, heart disease 19, bronchitis 9, marasmus 5. There were 12 deaths from violent causes. The number of children who died under one year was 42, under five years 68, persons more than sixty years 57; deaths in public institutions 56.

Cases of Infectious Diseases Reported in 1899 and 1900. — Diphtheria and croup, 1900, 4,977; 1899, 2,836. Scarlet fever, 1900, 1,710; 1899, 1,381. Phthisis pulmonalis, from May 17, 1900, 815; 1899, ——. Typhoid fever, 1900, 730; 1899, 765. Measles, 1900, 2,465; 1899, 4,110. Total number of deaths, 1900, 11,678; 1899, 11,167. Rate per one thousand, 1900, 20.82; 1899, 20.12. Diphtheria and croup, 1900, 537; 1899, 304. Scarlet fever, 1900, 181; 1899, 74. Typhoid fever, 1900, 143; 1899, 165. Measles, 1900, 88; 1899, 33. Phthisis pulmonalis, 1900, 1,407;[1] 1899, 1,236.

Appropriation for the Rutland State Sanatorium for Tuberculosis. — The Massachusetts State Board of Charity has reported to the legislature recommending an appropriation of $110,000 for a building at the Rutland Sanatorium to provide for 250 patients instead of 200 as at present. This includes provision for an administration building, for a laboratory and other much needed details. The report recommends that the institution be visited regularly by the board.

Diphtheria and Scarlet Fever Statistics, Somerville, Mass. — The Somerville Board of Health reports 520 cases of diphtheria and 231 of scarlet fever for 1900. The number of deaths was 967, showing an increase of 166 over 1899. There is still a large number of diphtheria and scarlet fever cases in Somerville.

Glanders in South Framingham. — Considerable agitation exists among farmers over the reported existence of glanders in the district about South Framingham, Mass. The Massachusetts Cattle Commission is making an expert investigation of the source of the infection.

Smallpox in Bridgeport, Conn. — Precautions are being taken to prevent a threatened epidemic of smallpox in Bridgeport. The health officers have established compulsory quarantine for all suspected cases. The disease is supposed to have been introduced from New York.

NEW YORK.

Superintendent of Bellevue. — Dr. George Taylor Stewart, for several years past superintendent of the Metropolitan Hospital on Blackwell's Island, has been appointed by Charities Commissioner Keller to the superintendency of Bellevue, Harlem, Gouverneur and Fordham hospitals. The former superintendent of Bellevue, Mr. O'Rourke, has been appointed deputy superintendent under Dr. Stewart. Dr. Robert W. Hill, who was detailed by the State Board of Charities to investigate conditions at Bellevue Hospital, on January 9th made a report in which he severely criticised the management of that institution. In the course of it he said: "Outside of the medical staff there seems to have been no pride in the service, and in consequence the whole tone of the institution has been very low. The investigation has shown that the whole system at Bellevue has been radically wrong.

[1] This includes general tuberculosis.

Nothing save a complete change throughout the staff of employés will be satisfactory, for with a few notable exceptions, inefficiency, callousness and idleness characterize those who are employed to do the work of the hospital. The tests of efficiency and zeal, of character and sobriety, have not been applied, and it is by these that the new superintendent can make Bellevue what it should be — a model hospital. New buildings are needed, but a new spirit and motive far more."

SMALLPOX AND VACCINATION. — Recently a mail carrier was found in the Melrose Lodging House on upper Third Avenue, suffering from smallpox. The Health Board officials promptly removed the patient and vaccinated every one in the building with the exception of two lodgers who refused vaccination. About a week afterwards, on January 8th, one of these men was attacked by smallpox, and on the following day the other, while of the many others who were equally exposed to the disease not one has as yet contracted it. The total deaths from smallpox since the beginning of the present outbreak now number 16.

INFLUENZA. — In consequence of the prevalence of influenza the Hospital Saturday and Sunday Association has issued a special appeal to the public for prompt and generous contributions for the thirty-nine hospitals which it represents, in order to enable them to meet the extraordinary expenses incidental to the epidemic, which has prostrated a large number of nurses and helpers. During the week ending January 6th, 1900, 8 deaths from influenza were reported in the city. In the corresponding week of this year there were 36.

TUBERCULOSIS AT THE ELMIRA REFORMATORY. — According to the report of the new Board of Managers of the Elmira Reformatory, tuberculosis has increased to an alarming degree among the prisoners, and the spread of the disease is attributed largely to the laxity of the prison physicians in not carefully examining the physical condition of the convicts on their arrival and in not separating the healthy from the diseased. The report also shows that insanity is on the increase in the institution.

STATE HOSPITAL FOR TUBERCULOSIS. — On January 10th the State Board of Health and the State Forest Preserve Board announced their approval of the site finally recommended by the trustees of the State Hospital for the Treatment of Incipient Pulmonary Tuberculosis for that institution. It is located at Raybrook, three miles southeast of Saranac village, and embraces 521 acres; while most of the property immediately adjoining is State land.

ALLEGED CENTENARIANS. — John Magee, born in Ireland January 1, 1800, died in Brooklyn January 9th. Nicholas McQuillen, also born in Ireland, died at Southold, Long Island, on January 11th, at the reputed age of one hundred and three. Mrs. Lucy Pollard, of New Brunswick, N. J., a pensioner of the War of 1812, in which her husband fought, died on January 10th, at the age of one hundred and one.

PRIVATE SANITARIUM FOR TUBERCULOSIS. — The first meeting in aid of the Stony Wolde Sanitarium for consumptive women and children was held at the residence of Dr. George F. Shrady, on December 10th, and was addressed by Dr. H. M. Biggs and others. It is proposed to raise a fund of $100,000, and purchase a hotel and cottages already built at Kushagua Lake, Franklin County, in the Adirondacks.

COLUMBIA UNIVERSITY. — At the monthly meeting of the trustees of Columbia University, held January 7th, the following appointments were announced in the Medical Department: Dr. James D. Voorhees, secretary of the faculty; Dr. Ernest V. Hubbard, assistant in pathology; Dr. Stuart P. Jessup, assistant in normal histology.

CARNEGIE LABORATORY. — At the meeting of the Council of the University of the City of New York, held the same day, it was announced that the alterations in the Carnegie Laboratory had been completed. The upper portion has been rebuilt, and the entire building refitted for the purposes of a bacteriological laboratory, through the generosity of Mr. Carnegie, the original donor.

MEDICAL ASSOCIATION OF GREATER NEW YORK. — At the annual meeting of the Medical Association of the Greater City of New York, held January 14th, Dr. J. Blake White was re-elected chairman for the Borough of Manhattan. The membership of the society, which by its bylaws is limited to 500, now amounts to 416.

Miscellany.

THE STUDY OF PSYCHIATRY IN NEW YORK STATE.

AT a meeting of the New York Neurological Society held January 1, 1901, the following report was read and unanimously adopted: The committee of the New York Neurological Society, appointed at the request of the president of the New York Commission on Lunacy, to offer suggestions as to a scheme of scientific study of mental diseases in connection with the State hospitals for the insane, begs leave to report as follows:

(1) It is to the interests of the State that original research work should be carried on in relation to insanity, in order that the science should be advanced, and better methods of prevention, treatment and cure discovered. This is of direct interest to the taxpayer, upon whom falls the burden of the care of the insane.

(2) There should be one central laboratory in the State, wherein the energies of the best scientific men in the various departments of medicine related to insanity should be devoted wholly and exclusively to the prosecution of original research.

(3) Such a laboratory, combining the labors of well-qualified workers in general pathology, neuro-

pathology, psychology, chemistry, anthropology, and other requisite branches, should be able to produce from year to year results which would be creditable to the State as a patron of science, as well as invaluable in advancing the knowledge of the methods of treatment and cure of mental disorders.

(4) Each hospital for the insane should have upon its staff of medical officers one physician whose sole duty it should be to conduct ordinary autopsies and to carry on the routine duties of a clinicopathological microscopist.

(5) The central laboratory, or pathological institute, should be freely open to any qualified scientific men, for the prosecution of original research work, under the direction of the laboratory experts, preference always being given to the qualified men in the State hospitals. But systematic teaching of fundamental principles should not be required from any of the departments of the laboratory. The scientific men in charge of the various departments of the pathological institute should devote all their energies to original investigation, and not be taxed, hampered, or interfered with by medical men who are able to obtain instruction in fundamental principles elsewhere, without cost to the State.

(6) The central laboratory for original research should be a part of a reception hospital for the insane, situated on Manhattan Island. — *Medical Record.*

CACODYLATE OF SODIUM AS A "CURE" FOR PHTHISIS.

THE *Medical Press and Circular* comments as follows upon the new preparation known as cacodylate of sodium, which has been used for other disorders than tuberculosis of the lungs, and is certainly to be regarded as a preparation to be used with caution:

"Of all the so-called 'cures' for consumption that have been foisted on much defrauded humanity none can be more dangerous than the cacodylate of sodium. As a matter of fact that compound, which contains no less than 55% of arsenious acid, is advertised in the public newspapers as a harmless cure for all stages of consumption. Dr. Murrell has put the matter to the test by prescribing 1 grain of the cacodylate thrice daily to a patient suffering from advanced lung tuberculosis. This small dose produced dangerous symptoms of arsenical poisoning, and, needless to say, left the tuberculous mischief unaffected. In his original paper advocating the use of the drug Gautier advocated the use of .75 gramme hypodermically several times a day, and stated that no arsenical poisoning resulted. Similar large doses (10 grains) are actually advised by the druggists who are advertising the cacodylate of sodium in the general press as a 'cure' for consumption. In view of Dr. Murrell's experience it is clear that the vendors of this fallacious and dangerous remedy are incurring a most serious responsibility. After the publication of this timely warning by an eminent authority upon the action of poisons, no druggist selling the cacodylate otherwise than on prescription can be absolved from any evil consequences that may follow from the administration of the drug. It is hardly possible to give too much publicity to the facts of this death-trap remedy, which affords a striking proof of the danger of self-medication."

Correspondence.

THE SUPRARENAL CAPSULE IN ORGANIC HEART DISEASE.

NEW YORK, January 7, 1901.

MR. EDITOR: I intend to publish a second paper on the use of the suprarenal capsule in organic heart disease. Will you kindly ask the readers of your JOURNAL to send me the reports of their cases as follows: (1) The condition of the heart and pulse rate; (2) the effect on the heart and pulse and pulse rate within ten minutes after the suprarenal powder, three grains, is chewed and swallowed, without water, by the patient.

Yours truly,

SAMUEL FLOERSHEIM, M.D.

218 East 46th Street.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JANUARY 5, 1901.

Deaths reported 2,777; under five years of age 726; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 624, acute lung diseases 531, consumption 321, diphtheria and croup 121, typhoid fever 63, diarrheal diseases 41, scarlet fever 28, whooping cough 14, cerebrospinal meningitis 7.

From whooping cough Philadelphia and Pittsburg 3 each, New York and Boston 2 each, Providence, Worcester, Somerville and Chicopee 1 each. From cerebrospinal meningitis Pittsburg and Boston 2 each, Philadelphia, Gloucester and North Adams 1 each. From scarlet fever New York 18, Boston 4, Philadelphia 3, Baltimore 2, Worcester 1. From typhoid fever New York 18, Philadelphia 16, Pittsburg 13, Baltimore and Boston 4 each, Providence 3, Worcester and Waltham 2 each, Springfield 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending

December 22d, the death rate was 16.1. Deaths reported 3,590: acute diseases of the respiratory organs (London) 396, diphtheria 103, whooping cough 76, fever 52, measles 46, diarrhœa 39, scarlet fever 33.

The death rates ranged from 10.1 in Derby to 22.3 in Birkenhead: Birmingham 17.5, Brighton 15.1, Bristol 15.2, Cardiff 14.5, Croydon 13.9, Gateshead 15.3, Halifax 15.5, Hull 15.3, Leeds 15.6, Liverpool 19.6, London 15.7, Manchester 18.9, Newcastle-on-Tyne 16.2, Norwich 12.3, Nottingham 15.7, Oldham 17.3, Plymouth 12.8, Portsmouth 13.4, Salford 22.2, Sheffield 18.8, Sunderland 15.2, Swansea 17.8, West Ham 11.6.

METEOROLOGICAL RECORD

For the week ending January 5th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 12, 1901.

F. ANDERSON, surgeon, ordered home and to wait orders, when recruiting duty is completed.

C. H. T. LOWNDES, surgeon, detached from the Naval Academy, January 14th, and ordered to the "Lancaster," *via* steamer from New York City of January 19th.

O. DIEHL, surgeon, detached from the "Lancaster" and ordered home and to wait orders.

B. R. WARD, passed assistant surgeon, detached from the Naval Hospital, Mare Island, Cal., January 17th, and to the Boston Yard.

J. B. DENNIS, assistant surgeon, ordered to the Naval Academy, January 14th.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING JANUARY 10, 1901.

WASDIN, EUGENE, surgeon. Granted leave of absence for fifteen days from January 14th. January 5, 1901.

WERTENBAKER, C. P., passed assistant surgeon. To proceed to Fontainebleau, Miss., for special temporary duty. January 5, 1901.

STIMPSON, W. G., passed assistant surgeon. To proceed to Cripple Creek, Col., for special temporary duty. January 4, 1901.

NYDEGGER, J. A., passed assistant surgeon. To proceed to Chicago, Ill., and report to medical officer in command for duty and assignment to quarters. January 5, 1901.

DECKER, C. E., assistant surgeon. Granted seven days' extension of sick leave from January 4th. January 7, 1901.

ANDERSON, J. F., assistant surgeon. Having been assigned to duty in the Immigration Service at Liverpool, Eng., relieved from duty in the U. S. Consulate at that port. January 5, 1901.

WALKLEY, W. S., acting assistant surgeon. Granted leave of absence for three days. January 8, 1901.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the society will be held in Sprague Hall at the Medical Library Building on The Fenway, on Monday, January 21st, at 8.15 P. M.

Paper by Dr. James G. Mumford, "The Story of the Boston Society for Medical Improvement."

Remarks by Drs. James C. White, Morrill Wyman, Clarence J. Blake, Reginald H. Fitz, George B. Shattuck.

All interested in the medical history of Boston are invited to be present.

ARTHUR K. STONE, M.D., *Secretary*, 657 Boylston Street.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The Section for Obstetrics and Diseases of Women will meet on Wednesday, January 23, 1901, at 8 P. M., in Sprague Hall, Boston Medical Library Building, 8 The Fenway.

Papers: Dr. H. O. Marcy, "Gynecology: Its Contribution to General Surgery."

Dr. Emma L. Call: "An Emergency Case of Cesarean Section in a Face Presentation Complicated with Uterine Fibroid."

Dr. F. A. Higgins: "My Experience with Antistreptococcus Serum in Puerperal Sepsis."

W. H. GRANT, M.D., *Secretary*, 419 Boylston Street.

RECENT DEATHS.

LUCIUS J. W. LEE, M.D., of Brooklyn, N. Y., a grandnephew of the late Prof. S. D. Gross, of Philadelphia, died of pneumonia on January 7th, in his sixty-fifth year. He was born in Easton, Pa., and was graduated from the Medical Department of the University of Pennsylvania. During the Civil War Dr. Lee served on the medical staff of Douglas Hospital, in Washington, D. C.

THOMAS BROWN WHEELER, M.D., of Montreal, died suddenly at the Murray Hill Hotel, New York, on January 10th, of apoplexy. He was seventy years old.

BOOKS AND PAMPHLETS RECEIVED.

The Harvard University Catalogue, 1900-01. Cambridge, 1901.

Railway Surgery in America. By Clark Bell, Esq., LL.D. Reprint. 1900.

Anginen durch den Friedländer'schen Bacillus. Von Dr. Emil Mayer. Reprint. 1900.

Abdominal vs. Vaginal Hysterectomy. By Henry O. Walker, M.D., Detroit, [illegible] Reprint. 1900.

Contributions of Irving C. Rosse, M.D., Washington, D. C., 1871-1900. One hundred and five titles.

Neglected Clinical Opportunities in American Medical Centres. By S. A. Knopf, M.D., New York. Reprint.

Mothers' and Babies' Hospital and Dispensary, Annual Report from January 1, 1899, to October 1, 1900.

Forty-fifth Annual Report of the Trustees of the Northampton Insane Hospital for the Year ending September 30, 1900.

Hernia, Undescended Testicle, Appendicitis and Gangrene of Bowel; Operation and Recovery. By C. W. Lillie, M.D. Reprint. 1900.

Panama and the Sierras; A Doctor's Wander Days. By G. Frank Lydston, M.D. Illustrated. Chicago: The Riverton Press. 1900.

The Thirty-first Annual Report of the State Board of Health of Massachusetts. Boston: Wright & Potter Printing Co., State Printers. 1900.

Abstract of the Proceedings of the National Convention of 1900 for Revising the United States Pharmacopeia, held at Washington, May 2, 3 and 4, 1900.

The Necessity of Expert Supervision of Medical Items Printed in the Daily Newspapers. By Walter L. Pyle, A.M., M.D., Philadelphia. Reprint. 1900.

Indications for the Drainage in Diseases of the Biliary Passages and the Technic of Operation. By J. E. Summers, Jr., M.D., Omaha, Neb. Reprint. 1900.

The Remote Results of Conservative Operations on the Ovaries and Tubes; An Analysis of Eighty-five Cases. By W. L. Burrage, M.D., Boston. Reprint. 1900.

Estimation of the Amount of Injury to the Earning Capacity of the Individual from Partial or Complete Loss of Vision. By Howard F. Hansell, A.M., M.D., Philadelphia, Pa. Reprint. 1900.

A Contribution to the Study of the Insect Fauna of Human Excrement, with Especial Reference to the Spread of Typhoid Fever by Flies. By L. O. Howard, Ph.D. Washington, D. C. 1900.

Thirty-second Annual Report of the Secretary of State of the Registration of Births and Deaths, Marriages and Divorces in Michigan for the Year 1898. Justus S. Stearns, Secretary of State. Edited by Cressy L. Wilbur, M.D. Lansing, Mich.: By Authority. 1900.

The Physician as a Scientist. A Compact Operating Case for Military Service, with a Description of Several New Instruments for the Same. Restitution of the Continuity of the Tibia by Transplantation of the Patella into an Extensive Osteomyelitic Defect. By N. Senn, M.D., Ph.D., LL.D., Chicago. Reprints. 1900.

A SHORT ABSTRACT OF THE EARLY HISTORY OF MEDICINE IN MASSACHUSETTS TO THE YEAR 1800.[1]

BY ELBRIDGE G. CUTLER, M.D., BOSTON.

I am indebted for my facts to the "History of Medicine in America," by James Thatcher, M.D.; the first volume of the Massachusetts Medical Society publication; "History of Early Medicine," by Josiah Bartlett, M.D.; and the second volume of the *Massachusetts Medical Society Transactions*.

The landing of the first emigrants at Plymouth, Mass., was December 22, 1620. More than a century and a half elapsed after the first settlement of the colonies before a single effort was made either by public authority or by the enterprise of individuals for the establishment of institutions for the education of physicians, or the regulation of the practice of medicine.[2] Our ancestors were strongly impressed with the importance of general education, and it was their constant solicitude to provide for institutions of learning as far as was practicable. But the welfare of the church and their political economy were made paramount to all other considerations. The peculiar motives which prompted their emigration to this country, the difficult circumstances they were called upon to encounter, and the depressed state of medical science in the countries whence they came, will furnish the most ample apology for their neglect of the means of improved medical education. Our colleges turned out graduates who repaired to Europe to complete their medical education in the public medical schools, and to qualify themselves to practise in the colonies.[3]

No medical libraries existed anywhere in the country, and it was seldom that students could have access even to the elementary works necessary to their instruction. No medical journal was published in America till near the close of the eighteenth century through which physicians could communicate the results of their experience or make known their improvements and discoveries; not even a newspaper was printed till the year 1704.[4] Hence it is not strange that we are so little acquainted with the character and practice of our predecessors.

The first physician of whom we have any account among the colonists was Dr. Samuel Fuller. He formed one of the company who came over in the first ship, and was a deacon in Rev. John Robinson's church. Whether he had enjoyed a collegiate education is uncertain, but he is said to have been well qualified in his profession; he was zealous in the cause of religion, and eminently useful as a physician and surgeon. He extended his benevolent labors not only to the sick among his intimate friends at Plymouth and the aborigines in the vicinity, but in 1628 and 1629, by the request of Governor Endicott, he twice visited the new settlement at Salem, where he manifested his skill and success in practice among the numerous sufferers from scurvy and other diseases introduced there by the ships on their arrival. He received the entire approbation of Govenor Endicott, and his letters of thanks for his useful services. In a letter to Governor Bradford, June 28, 1630, Dr. Fuller says: "I have been to Matapan (now Dorchester) and let some 20 of these people blood." What disease prevailed among them to require the loss of blood in the warm season of June we are unable to determine. In the year 1632 the settlers at Plymouth were visited by a disease which they called an infectious fever, of which upwards of 20 men, women and children died, among them being their pious and excellent physician, Dr. Fuller. The same disease proved very fatal also among the native Indians.

In the year 1633 Dr. Giles Firmer was a deacon in the Boston church and was esteemed as an able physician and a man of learning. In 1637 Dr. John Fisk arrived and settled in Salem, where he sustained a respectable character as a clergyman and physician. William Gager accompanied Governor Winthrop to Boston in the position of surgeon, where he died greatly lamented. At the first commencement at Harvard College, in 1642, Samuel Bellingham and Henry Saltonstall were graduated, and were afterwards honored with the degree of M.D. at European universities, and both were reputed learned and skilful physicians. Leonard Hoar was graduated at Harvard College, and repaired to England, where he studied medicine and received the degree of M.D. He returned to New England, and was for about two years president of Harvard College. Other M.D.'s were John Glover, 1650, Harvard College, who got his degree from Aberdeen and returned; Isaac Chauncey, 1651, from Harvard College, who came back from Europe with his M.D.; John Rogers, M.D., president of Harvard College, 1682–1684: it is uncertain if he practised; Charles Chauncey, president of Harvard College, 1652,—medical education in England,—who had six sons, all educated at Harvard, who all studied medicine and became eminent in their profession; several removed to England and did not return. Matthew Fuller in 1640 practised in Plymouth, removed to Barnstable in 1652, and died in 1678. He was appointed surgeon-general of the Provincial forces raised in Plymouth County in 1673, and was captain in 1675. Thomas Oliver, an elder in the Boston church, is mentioned with high approbation in Winthrop's journal as an experienced and skilful surgeon about 1644.

In 1646 the virtuous people in Boston were much grieved by the discovery of a disease in Boston with which, till then, they were entirely unacquainted, and which the venerated Winthrop in his journal says, "raised a scandal upon the town and country, though without just cause." This proved to be lues venerea. It originated with the wife of a seafaring man, who after childbirth was affected with ulcerated breast. Many persons were employed to draw this woman's breast, by which means about 16 persons, men, women and children were affected with this new and odious disease. The nature of the complaint was at length ascertained; but no physician could be found in the country who was acquainted with the method of cure; but it fortunately happened that at that very season a young surgeon arrived from the West Indies

[2] Bequest to Harvard College of Dr. Ezekiel Hersey, 1770.

[3] Harvard College was founded at Cambridge in 1638; William and Mary College of Virginia in 1691; Yale College in Connecticut in 1700; Princeton College in New Jersey in 1746; Philadelphia College in 1754; King's, now Columbia, in New York in 1754.

[4] The first newspaper printed in America was the Boston News-Letter, April 24, 1704, by B. Green; the first in Pennsylvania, December 22, 1719; the first in New York, October 16, 1725; the first in Charleston, S. C., 1730; in Rhode Island, October, 1732; in Connecticut, 1755; in New Hampshire, 1756.

who had been experienced in the disease, and he soon performed a cure. In the summer of 1647 an epidemic spread through the country among English, French, Dutch and Indians. It resembled a cold, attended with slight fever (probably influenza). Winthrop says, "Those who were bled or used cooling things died, those who took comfortable things for the most part recovered in a few days. Not a single family, and but a few persons escaped an attack of this epidemic; about 40 or 50 died in Massachusetts, and about the same number in Connecticut."

Thomas Thatcher came over to New England in 1635, educated for the ministry, also received a medical education, and was regarded as an eminent divine and learned physician. He gained great eminence in both professions, and was also prominent in the learned languages. He published a work entitled "A Brief Guide in the Smallpox and Measles," in 1677, which is the first medical publication found on record in New England, if not in America. As an illustration of the state of medicine in France in 1686, nearly seventy years after the settlement of Massachusetts, Felix, a surgeon, and Fagon, a consulting physician, were rewarded with $40,000 for a successful operation for fistula in ano on Louis XIV of France, in consequence of which a national thanksgiving was religiously observed.

At this time also the royal touch was considered as the only cure in scrofula. In May, 1682, notice was given in a London gazette that as the weather was growing warm, His Majesty would not touch any more for the king's evil till after Michaelmas; and in 1687 an indigent citizen of New Hampshire, having tried every other means without effect, petitioned the legislature for aid to transport him to England for that efficacious remedy.

In 1721 inoculation for smallpox was first regularly adopted in England by Mr. Maitland in April, on the young daughter of Lady Mary Wortley Montague, who had lived in Constantinople, and had become acquainted with the method of inoculation practised by some Turkish women, and satisfied of its safety and salutary effects, had it done on her young son in the East in 1717. The above was the first time it was done in England. Dr. Cotton Mather, the learned divine of Boston, about the same time, having read in the *Philosophical Transactions*, printed in London, an account of inoculation for smallpox by Timoni and Pylarini in Turkey, communicated the information to several physicians of Boston, who treated the subject with contempt. He then recommended to his friend, Dr. Zabdiel Boylston, to adopt the practice. Accordingly with the little information which he could obtain from that publication, and in the face of the most violent opposition, on the 27th day of June, 1721, Dr. Boylston inoculated first his only son, about thirteen years of age, and 2 negro servants, in which he was entirely successful. This confirmed in his own mind the safety of the proceeding, and in 1721 and the first part of 1722, Dr. Boylston inoculated 247 persons, and 39 were inoculated by others in Boston and vicinity; of this number only 6 died, and several of these were supposed to have taken the infection before inoculation. In the same time 5,799 took the disease in the natural way, of whom 844 died, and many who recovered were left with broken constitutions and disfigured countenances. The degree of odium and persecution which Dr. Boylston brought upon himself by this very laudable innovation is almost incredible. His house was attacked and he himself assaulted in the streets, loaded with all kinds of abuse and execrated as a murderer. A bill was brought before the legislature to prohibit the practice of inoculation under severe penalties, and it actually passed the House of Representatives; but some doubts existing in the council, its progress was arrested, and it never became a law. Dr. Boylston was repeatedly summoned before the selectmen of Boston and received their reprehension.

Not only did he suffer the greatest indignity from the populace but his professional brethren formed a powerful combination against him, though repeatedly invited to visit his patients and examine them to their satisfaction. The novelty of the subject and the strong prejudices existing caused much public agitation, and involved both clergymen and physicians in a spirited and intemperate controversy. The clergymen in general, however, acted an honorable part and many became zealous advocates of the new practice, while most of the medical fraternity were its active and violent opposers. The newspapers teemed with pieces on both sides of the controversy, and from the opponents of inoculation issued some of a virulent and scurrilous character. It is interesting to note that the *New England Courant*, printed by the Franklins (the young philosopher being one of the editors), was under the influence of the physicians, who abused the clergy for their interference in the controversy. He, however, persevered and finally enjoyed the results of his very useful labors. He finally was invited to London, and received all sorts of honors. While in London in 1726, on request of the Royal Society, he published an historical account of the smallpox inoculation as practised by him in Boston, dedicated to Princess Caroline. It was reprinted in Boston after his return, and a copy was deposited in the Harvard College Library by Ward Nicholas Boylston. The introduction of inoculation of smallpox may be regarded as an epoch in medicine, and to Dr. Zabdiel Boylston alone is due the credit of having firmly established it in this country.

In the year 1752 the country was again visited by an epidemic of smallpox, and by order of the magistrates an account was taken of all who were affected by the disease, either by the natural way or by inoculation in Boston, and rendered on oath. It appears that the number of inhabitants was 15,734. The whole number of smallpox patients the natural way was 5,544, of which 514 died. The number of inoculated was 2,113, of which 30 died. In 1764, according to Dr. Gale, 3,000 persons were inoculated and only 8 died, chiefly children under five years of age. Public hospitals for smallpox inoculation were opened in the vicinity of Boston in 1764, one at Point Shirley, by Dr. Wm. Barnet, and one at Castle William in Boston Harbor by Dr. Samuel Gelston, of Nantucket. In 1792 smallpox again visited Boston, and in three days the whole town was inoculated, so great was the fear of the disease. There were 9,152 inoculations, and 165 deaths occurred, chiefly in the families of the poor, many of whom were destitute of the comforts of life.

In 1735 and 1736 the disease called angina ulcusculosa (angina maligna) prevailed extensively throughout the country in its most malignant form, and in Massachusetts alone about 1,000 persons be-

came its victims. On this occasion calomel was for the first time administered as a remedy, and attended with the happiest results, arresting in a surprising way the fatal tendency of the disease. Dr. William Douglass published a valuable practical essay detailing the characteristics of the method of treatment of this alarming complaint.

Among the earliest publications on medical subjects in America was an essay on fevers published in Boston in 1732 by Dr. John Walton. Dr. John Cutler was long an eminent physician and surgeon in Boston. He was the preceptor of several of the early physicians; among them was Dr. Zabdiel Boylston. In 1781 old Continental paper money was used and physicians had great difficulty from the fluctuating value of it. The physicians of Boston instituted a club, the meetings of which were held in the Green Dragon Tavern. Physicians' fees were low, and when paid in depreciated paper money little or nothing could be realized from them. The fee for a visit was one shilling and sixpence, afterwards increased to two shillings. Midwifery and capital operations were at a guinea, with charges for after visits. The first fees established by the medical club were fifty cents for a visit; if in consultation, one dollar; rising and visit in the night, after 11 o'clock and before sunrise, double fee; obstetrical case, eight dollars; capital operation in surgery, five pounds; reducing a dislocation, or setting a fractured bone, one guinea; bleeding, opening an abscess, extracting a tooth, fifty cents, and the usual fee for visit was added. All accounts were to be calculated in hard money, and if paid in paper, according to such agreement as could be made with the parties. The profession was much benefited by these regulations.

The Massachusetts Medical Society was established in 1781, with power to elect officers, examine and license candidates for practice, hold real estate, and perpetuate its existence as a body coporate forever. This auspicious event was effected by an application to the legislature of thirty-one distinguished physicians from various parts of the State (their seal adopted in June, 1782, was a figure of Esculapius in his proper habit pointing to a wounded hart nipping the herb proper for his cure, motto, "*Natura duce*"), and is an interesting era in our history. The society was organized in June, 1782, and Edward A. Holyoke chosen president. The fellows were enjoined to communicate important cases, and the faculty at large invited to a familiar correspondence; circular letters were sent to similar societies in our own and in foreign countries, which were respectfully reciprocated. In 1785 corresponding and advising committees of the society were appointed for the different counties, in several of which associations were formed for meetings, reading dissertations, etc. In 1789 the society was authorized to point out and describe such a mode of medical instruction as might be deemed requisite for candidates, previous to examination. It was determined that every pupil should have a competent knowledge of Greek, Latin, the principles of geometry and experimental philosophy, and the period of instruction should be in no case less than three years, with attendance on the practice of a respectable physician. Publications were made triennially of authors to be studied, by which the most valuable modern productions were extensively circulated. The censors met for examination and licensing candidates once in four months. The first licentiate was admitted in 1782.

In 1790 the first number of medical papers containing a selection of important communications was published, but for want of funds a second did not appear till 1806. A third was printed in 1808, completing the first volume of the Massachussets Medical Society publications.

Dr. Ezekiel Hersey, of Hingham, who died in 1770, bequeathed £1,000, and his widow at her death a like sum, to be applied to the support of a professor of anatomy and surgery at the University at Cambridge. Dr. Abner Hersey, of Barnstable, who died in 1786, and Dr. John Cuming, of Concord, were also donors to the amount of £500 each for the same laudable purpose, and William Erving, Esq., of Boston, left £1,000 toward the support of an additional professor. In conformity with the views of the patrons and donors, professors of talents and character were in 1782 appointed, by whom lectures on the several branches were regularly delivered and students received the honors of the institution. In 1780 Dr. John Warren, while surgeon of a military hospital in Boston, commenced a course of anatomical lectures, and in the following year they were attended by the students of the university. Dr. Warren furnished a plan for a medical school, which was adopted by the corporation of Harvard College, and in 1783 he was appointed first professor of anatomy and surgery; Dr. Benj. Waterhouse, professor of the theory and practice of physic, and Dr. Aaron Dexter, professor of chemistry. This was the first essay made in New England for the establishment of an institution for medical education. George Holmes Hall and John Fleet were the first who were admitted in course to the degree of Doctor in Medicine at the university in the year 1788. In 1809 Drs. John Collins Warren and John Gorham were repectively inaugurated adjunct professors of anatomy and chemistry.

To go back a few years, the discovery of vaccination by Edward Jenner, a physician of Berkely, in Great Britain, was transmitted to this State in 1799. In July, 1800, Benj. Waterhouse, professor of the theory and practice of physic at the Medical School, procured vaccine matter from Bristol, England, and first vaccinated his son, the first person to be so treated in the United States.

One is at once impressed with two things in reading what precedes: (1) The prominent position which Massachusetts held in the advancement of medicine in the early days, and (2) the close relation between the physician and the clergyman, the two professions being often united in one individual, a most noted instance being Manassah Cutler, of Hamilton, Mass.

THE GREAT TOE (BABINSKI) PHENOMENON: A CONTRIBUTION TO THE STUDY OF THE NORMAL PLANTAR REFLEX BASED ON THE OBSERVATION OF ONE HUNDRED AND FIFTY-SIX HEALTHY INDIVIDUALS.

BY MORTON PRINCE, M.D., BOSTON,
Physician for Nervous Diseases to the Boston City Hospital.

FOR the general reader who has not followed late neurological literature I will say that the Babinski phenomenon is a modification of the normal plantar

reflex. Stroking the sole of the foot normally causes a *flexion* movement, *if any*, of the toes, particularly of the four outer toes. Babinski pointed out that when the motor paths in the cord are diseased, as in hemiplegia and spastic paraplegia, stroking the sole, more particularly the outer surface, causes just the opposite movement, namely, "extension of the toes, particularly of the great toe."

This phenomenon promises to be of great value as a test of organic disease of the motor paths. Nevertheless there seems to be some difference in the understanding as to exactly what constitutes a Babinski phenomenon. This difference and various other factors which complicate the phenomenon are the probable cause of the different opinions held regarding the value of the test.

According to the *definition* of Babinski[1] extension of the outer toes may suffice for the phenomenon which is described as an "extension of the toes, particularly of the great toe." But he further states while flexion "predominates generally in the two or three outer toes, extension is *ordinarily*[2] more pronounced in the first or the first two toes." This language would imply that extension of the outer toes without that of the great toe, which may be sometimes observed, is of similar significance, or at any rate that sometimes extension is more pronounced in the outer toes. At least this interpretation is not uncommonly met with. Walton defines the phenomenon as an "extension of the great toe with or without extension and separation of the other toes." On the other hand, in the literature the phenomenon is almost always spoken of as the phenomenon of the *toes* (*phénomène des orteils*, *Zehen-Phänomen*), or extension of the toes, as if this movement of the smaller toes was of equal significance.

This difference is practically of importance, for according to Walton's definition, extension of the outer toes without including the great toe would not be a true "Babinski." While this may not be strictly true, I am satisfied that the phenomenon as defined by Walton is the form in which it is always, or almost always, of pathological significance and therefore of most clinical value, as will appear from the following observations.

From private conversation, I should also judge there was still considerable individual difference in the conception of the character of the extension movement constituting a Babinski phenomenon. Dr. Walton insists that the extension must be constant and deliberate, and marked; others consider any extension movement sufficient, even if not persistent (as with the knee jerk). Thus Babinski describes as a variation of the phenomenon one which consists of "sometimes flexion and sometimes extension, the first excitations causing flexion." Another variation is "extension from stroking the outer surface, flexion from the inner."

To acquaint myself more fully with the exact character of the normal plantar reflex, and more particularly to determine whether the Babinski phenomenon or any extension movement of the toes occurs in normal individuals, I have lately examined the reflex in 156 presumably healthy men between the ages of twenty-two and thirty-three years, all candidates for civil service examinations. For the purposes of the investigation only the reflex movements of the toes and ankle were noted. Those of the leg were disregarded.

As a result of these observations I have been able to satisfy myself that one cause of the discrepancies in the reported observations of different observers is that there may be two distinct plantar reflexes, one of which is probably cerebral and one is spinal. Both may be absent. The normal spinal reflex movement of the toes in the adult is always, as shown by Babinski and others, flexion; the normal cerebral reflex is generally, if not always, extension of the toes, with the same movement of the foot. If precautions are not taken the cerebral reflex may mask the spinal reflex, and give erroneous results, that is, override the spinal flexion and produce an extension.

The cerebral reflex can generally, not always, be inhibited by an act of will, and thus leave the spinal free. When this was done in these observations an extension of the great toe was never observed.

The 156 subjects were studied in two different groups. The method employed on the first group varied somewhat from that employed in the other and gave correspondingly different results of some interest. The first group (examined in May last) comprised 64 men. In 3 of these an extension of some or all of the four outer toes occurred, while the big toe remained motionless or was flexed. In 1 there was extension, though slight, of the big toe in each foot. The knee jerk was noted as plus, but no ankle clonus. In 1 other there was an extensor response, but the notes fail to state whether of the big toe or of the others. A dorsal flexion of the ankle was noted as frequent. Reference will be made to this again. In the remaining 57 cases, the response, if any, was flexion.

Noting the significance of the fact that in 4 of the 5 subjects in whom extension occurred the movement was only of the outer toes, it seemed probable that this extensor reaction was far too frequent to be a true spinal reflex, and was due to some other physiological arrangement. The subjects were more or less nervous and excitable, and I was satisfied that I did not take sufficient precautions to see that the muscles were thoroughly relaxed, and the subjects in mental repose.

Accordingly, the observations were repeated on 92 subjects, similarly candidates for civil service examination, and presumably with healthy nervous systems.

Special care was taken to see that the subject relaxed his muscles and he was warned to guard against all involuntary movement and subjective response to tickling sensations; at the same time care was taken not to excite to an uncomfortable degree the skin.

In not one was an extension movement of the great toe observed. In only one was a *distinct* and *marked* extension of the four outer toes noted. The great toe in this case was either immobile or showed occasional slight flexion. The knee jerk was normal and there was no ankle clonus, but the subject was designated in the notes as nervous. In another case *slight* extension occurred at times in the outer toes of one foot. Both great toes showed no reflex movement whatever.

The result in general was that whatever plantar reflex was obtained was very largely limited to the toes, and general signs of ticklishness were not obtrusive. A pointed stick was used for stimulation.

At first before the subjects learned to relax their

[1] Followed by Collier, Langdon and others.
[2] Italics not in original.

muscles, etc., in some cases there were extensor movements of toes, including the great toe and foot, which masked the true spinal reflex. As soon as the subject exercised mental control these movements tended to cease, and that of the great toe always ceased. In the other toes extension was only observed in the 2 cases mentioned. In the first series of 64 cases dorsal flexion (extension) of the foot was common. In a series of 72 cases in which precautions to exclude the cerebral reflex were taken this tibialis anticus contraction was noted as present only 6 times, and in 4 of these the subjects are specially noted as "ticklish" or "nervous" or both.

It seemed very evident that the extension movements (toes and foot) noted were proportioned to the ticklishness or nervousness of the individuals. These movements have been described as semi-voluntary (Walton). This is an unfortunate term and means nothing.

They seem to me to be properly a cerebral reflex, and similar to dodging the head or closing the eye before an expected blow. Such movements are not voluntary or semi-voluntary, but automatic, for volition sometimes cannot prevent them. That these particular toe movements are cerebral is further suggested by the fact that they occur in proportion to the degree of "ticklishness." That they are not "voluntary" is shown by the fact that they require a strong effort of will to inhibit them, and sometimes cannot be inhibited at all. (I have noted that in subjects mentally dull from disease and unable to inhibit but still ticklish, these movements are marked.)

But whether cerebral or spinal the point should be emphasized that in not a single case was extension of the great toe noted when properly examined.

It may be said, then, that when proper precautions are taken to inhibit the cerebral reflex, extension of the great toe never occurs, or, more correctly, it was not observed once in 92 individuals, and only once in the first group of 64, when it was *slight*, and in all probability a cerebral reflex, as it was in this group that insufficient precautions were taken.

Extension of some of the other toes occurs occasionally in health (2 out of 92 subjects and 3 out of 64). But in some of these cases at least, if not in all, it is a cerebral reflex. Nevertheless, it is not always practical to make this distinction clinically.

The significance, then, of the Babinski phenomenon, consists in the extension of the great toe. To emphasize this the best term would be the *great toe phenomenon* (like knee jerk, ankle *clonus*, etc.). But from this it does not follow that extension of the other toes may not be of pathological moment, for though it may be physiological (cerebral?), it may be due to disease of the motor tract as with the great toe. In a case, for example, of meningeal hemorrhage from a pistol shot wound, a very extreme extension of all the toes, as intense and prolonged as I have ever seen, was later, after removal of the clot, followed by extension of only the outer toes, and then stroking caused at first extension succeeded by flexion; this was evidently the remains of the Babinski. The significance of extension of the outer toes alone must therefore be a matter of consideration in each case. Slight extension of the outer toes without that of the big toe I have observed in obscure cerebral disease without being able to determine the significance of the phenomenon.

The recognition of a cerebral as well as spinal plantar reflex seems to the writer of practical moment. The one may obscure the other.

Looking at the two reflexes from a biological point of view, the theory is plausible that the cerebral reflex is one of retreat from a hurtful stimulus, a reflex which has grown out of a conscious volitional impulse. The spinal reflex is probably that of assistance, such as automatic grasping the limb of a tree or other object.

Absence of any toe reflex. — The number of cases in which no toe reflex was observed is noteworthy. Of 72 consecutive cases no reflex at all of the big toe could be obtained in 52. Of 92 cases, no reflex of any toe occurred on either side in 18 cases, on one or both sides in 27 (30%).

This is slightly higher than Walton's figures. My belief is that the frequency of the plantar (spinal) reflex, so far as it concerns the toes, has been exaggerated owing to several sources of fallacy being overlooked, namely: (1) Mistaking the cerebral for the spinal reflex; (2) in stroking the sole it is not difficult by moderate pressure over the first phalanges to cause a purely mechanical flexion of the toe; (3) if the stroke is made from the toe towards the heel pulling on the skin, when inelastic, will do the same.

A CASE OF OBLITERATION OF THE RIGHT URETER BY A CALCIFIED FIBROID; REMOVAL OF FIBROID AND IMPLANTATION OF THE URETER INTO THE BLADDER; RECOVERY.[1]

BY MAURICE H. RICHARDSON, M.D., BOSTON.

THE following case illustrates some of the dangers of leaving an old fibroid to itself. The patient, Mrs. E. M. W., age fifty-eight, had always been well up to ten years ago. She had had two children and no miscarriages. Menstruation had always been regular. The menopause was at the age of forty-five. Ten years ago she noticed in the right lower abdomen a tumor, which gradually increased in size. At intervals she suffered more or less pain from this tumor. Three years ago she began having frequent and painful micturition. During the past three years the pain in the lower abdomen has been much more frequent and more severe. At times she has been unable to hold her water. The urine has been increasing in cloudiness and the odor has become foul. There has been loss of weight and appetite. The bowels have been constipated.

On examination I found a large fluctuating tumor of the lower abdomen. The signs of fluid were so marked that I was of the opinion that the tumor was ovarian. The woman's general condition was fairly good. I advised operation, but felt somewhat doubtful as to the ease with which the tumor could be removed.

On exposure the tumor proved to be a fibroid of the uterus, upon which — or a part of which — was a large cyst. The tumor was either a fibrocyst of the uterus, or a uterine fibroid in close connection with a cyst of the broad ligament. The tumor was deeply and broadly attached and separation seemed impossible. The deeper portions in the right side of the pelvis were evidently calcified, being of stony hard-

[1] Read before the Obstetrical Society of Boston, November 20, 1900.

ness. Ten years ago I should have abandoned the operation, and wisely so. Indeed, before this operation was completed, all concerned in it would have been glad if it had never been undertaken. Inexperience in such an operation would, I am sure, have made it a fatal one.

Separation of the tumor became more and more difficult as the calcified portions were reached. The areas of the tumor deep in the right broad ligament were closely attached to the right and anterior portions of the pelvis. Separation was made with the fingers carefully pressing between the capsule of the tumor and contiguous structures. When the solid and calcareous masses were reached, enucleation became still more difficult. It was at this point in the operation that clear fluid was noticed escaping rapidly and in large amounts from the depths of the dissection.

The orifice from which this fluid was flowing was easily recognized, and its edges grasped. Dissecting backward I found it to be the right ureter, which apparently ended at the separated calcified masses. Bepond this point, which was perhaps an inch or more from the bladder, no distal orifice of the ureter could be found, though most careful search was made for it. Above the orifice the ureter was dilated and tortuous, and the pelvis of the corresponding kidney much dilated. I supposed that the injury to the ureter was caused by a transverse tear, the ureter being presumably situated at an angle with the plane of the separated surfaces. It seemed, however, perfectly evident, finally, that the ureter ended at the plane of cleavage, and that separation at that plane tore across the obstructed end. However that may be, the problem was not unlike that of a divided ureter, except that end-to-end suture was impossible, for no distal end could be found, as I have said. It was fortunate perhaps that end-to-end union was impossible, for such an operation deep in the pelvis is not likely to succeed. The proximal end for one inch or more was freed from the resisting tissues in which it was imbedded until it could be brought easily to the collapsed bladder. A small opening was then made into the bladder, into which about half an inch of the lax ureter was thrust. The bladder about the ureter was then carefully and accurately sutured to the side of the ureter, the end of which was of course projecting about half an inch into the bladder. The sutures were of fine silk applied interruptedly. Separation of the tumor at the left soon demonstrated that it made a part of the sigmoid flexure. Removal, therefore, left a gap in that viscus, which was closed by a few silk sutures.

The whole operation was extremely difficult. Had not the ureter and the bowel been involved, enucleation of the tumor itself would have seemed sufficiently formidable. With the added complications, recovery seemed too much to expect. Fortunately, the most unpromising cases often do the best, and this was one of them, for convalescence proved — to use a much overworked word — uneventful.

The plan which I have always followed in pelvic surgery has made operations of ureteral repair extremely infrequent in my experience. This plan, which has everything to commend it, is to make the dissection of the deep pelvis — like that of the deep neck — in the full light of day, where every structure can be recognized as the dissection proceeds. The cases in which this deliberate dissection cannot be made, or in which the structures are too changed for recognition, are extremely infrequent.

A CASE OF VESICAL IMPLANTATION OF THE URETER BY DUDLEY'S FORCEPS METHOD AFTER THE FAILURE OF SEVERAL PLASTICS.[1]

BY EDWARD REYNOLDS, M.D., BOSTON.

MRS. L., forty-five years old, was sent to my office, August 21, 1900, by Dr. W. D. Madden with the following history. She had always been a well woman until the birth of her only child seven years ago. During the next year she suffered from some pain in one groin, which was diagnosed as due to ovaritis, for which she received somewhat prolonged local treatment without relief, and was finally advised to have an ovary removed by vaginal incision. She went accordingly to a hospital in this city, was etherized and operated upon, but some unforeseen difficulties turning up in the operation, a complete vaginal hysterectomy was done. The operation was followed by severe and increasing colicky pain in the left back, which terminated in the discharge of a large amount of urine on the removal of the vaginal stitches, since when there always has been a constant leaking of urine from the vagina. The following year the same surgeon operated either three or four times (the patient is not sure which), for the closure of a vesicovaginal fistula, but always with the result of having one small pinhole leakage persist in the middle of the union. A year ago she saw another surgeon, who told her that the fistula was ureterovaginal, and that an operation was too dangerous to be thought of. During the past year she has suffered unintermittently from eczema, extending from the vaginal vault down the inside of the thighs almost to the knees, and at the time she came to my office, the thighs were swollen, excoriated and bleeding.

Under the use of frequently changed vaginal tampons to absorb the urine and simple drying powders to the thigh, the eczema improved with extreme rapidity, and on August 25th she entered my wards at the Boston City Hospital, with the external skin in very fair condition, and the vagina, though still irritated and secreting a slightly purulent secretion, nevertheless much improved and fairly normal looking. The vagina was short and senile, with exceedingly thin vaginal walls and vault. The left side of the vault was a mass of tough cicatricial tissue from the repeated operations, in the centre of which could be seen an orifice, of a calibre of not more than 4 or 5 French, from which urine leaked intermittently as from a ureter, except when the patient bore down, when it appeared in quantity as though from the bladder. The vagina was dressed with oleate of zinc and iodoform gauze, and on the 27th I thought that it was in sufficiently normal condition to warrant an exploration of the fistula. The probe soon showed that in addition to a channel which passed upwards and backwards and was undoubtedly the ureter, there was another which turned forwards towards the bladder, though I could make nothing pass it. A catheter was inserted into the ureter for about one inch, and a

[1] Read before the Obstetrical Society of Boston, November 20, 1900.

specimen of urine collected, which proved to be of smoky color, containing numerous normal blood cells, probably due to trauma from the probe, a few abnormal blood cells and leucocytes, with about the amount of albumin which would be explained by the presence of the fresh blood. Nothing else abnormal was found.

On August 28th the patient was etherized, and after failing to pass a catheter into the bladder from the vagina, I exposed the bladder with a Kelly cystoscope, and easily passed a fine catheter from the ureteral orifice in the bladder back into the vagina. Another was passed into the ureter through the fistula, after a slight dilatation of the cicatricial opening in the vaginal vault, the two thus entering through the same opening. After an incision through the mucous membrane of the vagina completely surrounding these catheters, I was able to follow the ureter both ways under the guidance of the catheters. The distal end was traced into the bladder wall, after dissecting it for about one quarter inch. The proximal end was separated from the dense cicatricial tissue in which it lay, for about one-half inch with the greatest difficulty, and at continual risk of opening into the peritoneum (which on account of the probably infected character of the urine and vaginal secretion, I was of course very anxious to avoid), and having gained enough to be able to bring the ureter into contact with the bladder wall without tension, I thought it unwise to increase the risk by further dissection. The catheter was then withdrawn, the vesical end of the ureter was dilated by passing a No. 20 French bougie through it, the island of mucous membrane was cut off, thereby separating the two ends of the ureter, the vesical end of the ureter was dilated to No. 15 French by a bougie, a provisional stitch was passed through the renal end, drawn into the bladder through the dilated ureteral orifice and out through the urethra. Tension on this easily drew the renal end of the ureter into the bladder, inverting the vesical end of the ureter, and thus resulting in the approximation of a considerable extent of raw surface. The ureter was now fastened to the bladder wall by two sutures of fine catgut and every effort was made to take off tension by firm and exteusive coaptation of the surrounding tissues with many catgut sutures. No catheter was inserted, the patient being left to pass water voluntarily. A vaginal douche of weak corrosive solution was given daily; the patient was kept on salol and urotropin, with free use of cream of tartar water.

The patient had a slight run of pyrexia after the operation, varying from a little above 99° in the morning to nearly 101° at night. The urine became dark and cloudy, and on the 31st, four days after operation, it was distinctly smoky, and the sediment contained many leucocytes and abnormal blood cells, and hyaline and granular casts with fat and leucocytes adherent. The next day there was a considerable amount of pus and urates macroscopically and a small leak from the vagina.

On November 2d, the sixth day, the urine was slightly decomposed, containing amorphous urates, but the temperature was barely above normal. The vaginal wound had separated. Three weeks later the urine was still high colored, with a few red blood corpuscles and leucocytes, and a little calcic oxalate, but no casts. The vesical end of the ureter had become obliterated so that there was no regurgitation from the bladder, but the renal end was still discharging as before into the vaginal vault.

On October 29th I again made an incision into the vaginal vault and readily freed the ureter to the point which I had reached before, but again feared to pursue it further into the cicatricial tissues amid which it lay. I then freed the bladder from the tissues behind it for some little distance above the vaginal cut, made a small incision through the vesical wall, passed a pair of ordinary though rather fine-pointed artery forceps through the urethra into the bladder, and then separating them slightly, passed one blade out through the cut in the posterior vesical wall. The free end of the ureter was then threaded upon the projecting blade of the forceps, the forceps closed and the handles tied. The closing of the forceps carried the ureter very high up upon the bladder wall, and left a very deep vaginal wound, which was sutured together with many layers of running buried sutures. The operation was followed by three days of pyrexia, similar to that which followed the first operation, at the end of which time the urine contained pus, triple phosphates and casts in abundance. It was passed voluntarily and easily from the start.

On November 11th, thirteen days after the operation, the urine contained a few casts, a little pus, and of course a trace of albumin, but was otherwise essentially normal. The wound was firmly healed. Light traction was made upon the clamp every day in the hope of bringing it away, but without success, until on November 18th, the twentieth day after the operation, it was opened and immediately came away without effort. On November 20th, two days after the removal of the clamp, I made a careful endoscopic examination of the bladder, which was kindly repeated for me by Dr. C. M. Green; to my astonishment we found the ureteral insertion represented by a minute orifice surrounded by a spot of reddened mucous membrane about the size of a split pea. The rest of the bladder was entirely normal, and except for the high situation it would have been difficult to distinguish the new ureteral orifice from a normal one. A few days later the patient was discharged well.

When, about a year ago, this operation was described to this society, by Dr. E. C. Dudley, of Chicago, I must own that it appeared to me a very effective, but perhaps crude procedure. The chief objection to it then seemed to me to be that the grasp of the forceps must necessarily cause sloughing, and thus leave at the point where the ureter entered the bladder a wide gaping slit instead of the normally small orifice. My cystoscopic examination of my own case has convinced me that although the blades of my forceps were apparently tightly closed, there must have been enough nutrition in the portion of the bladder wall between the jaws to enable it to live, thus avoiding a slough, but securing an absolutely firm union of the ureter with the bladder.

The chief risk of failure in ureterovesical implantation is always from the slipping away of the ureter, owing to the thinness of its walls and the consequent difficulty in its secure suture to the bladder. This danger is entirely obviated by the Dudley method of securing the ureter and bladder together by forceps. The presence of the forceps must at the same time direct the stream of urine into the bladder, and in this case, at least, its presence in the bladder caused

no discomfort. (This could, I think, hardly be the rule.) The high position given to the ureter and the tension upon it, due to the closing of the forceps, also produced a very deep and therefore extensive surface for union between the bladder and vaginal wall. In this case the ureter and kidney had evidently been infected during their long drainage into the vagina, and it is probable that the loss of union after the first operation was due to infection of the wound by the decomposed urine which succeeded each operation; under these circumstances the case was probably peculiarly well adapted to show the advantages of Dudley's forceps operation.

PREGNANCY FOLLOWING REMOVAL OF BOTH OVARIES AND TUBES.[1]

BY M. A. MORRIS, M.D., BOSTON.

THE reader wishes to thank the society for the privilege which permits him to present to its members the story of a rather unusual case of pregnancy, following removal of both ovaries and tubes. The medical journals of the past twenty years or so have furnished reports of a small number of similar cases, some of which may be referred to, as they have taught the necessity and the advantage of conservatism in dealing with surgical diseases of the ovaries and tubes, and have stimulated closer observation and study of these organs.

Mrs. J. A. G., came under my care about May 1, 1898, on account of dysmenorrhea. One of her sisters had died of pulmonary tuberculosis, otherwise her family history was unimportant. She first menstruated at the age of fourteen years, and regularly thereafter, with slight pain, the flow continuing a week. She had been married five years, and had a healthy boy four years old. She had never been well since the birth of her child, had been attended in labor by an ignorant woman, and remained in bed only seven days after that event. During the next three weeks she was in bed most of the time on account of weakness, pains in both iliac and hypogastric regions, of a bearing down and dragging character, and an intermittent, bad-smelling, brown vaginal discharge. For two years previous to my visit she had dysmenorrhea, the pain being most severe in the region of the right ovary, beginning with, and lasting through, the menstrual period. During the previous seven months sexual intercourse had been productive of pain, as she said, "in the back passage"; the menstrual flow had been regular, profuse, painful, and continued seven days; she had lost flesh. At my visit her countenance was indicative of fairly good health, her pulse was 76 and temperature 99⅘, heart and lungs were negative. An examination of the urine, made later, was negative.

Vaginal examination revealed slight laceration of the cervix, and a small amount of discharge from its glands. The uterus was anteverted and fixed, so that it was immovable laterally, but movable, to a limited degree, anteroposteriorly. The body was moderately tender. On the right of the uterus was, apparently, a cystic ovary, and a thickened tender tube; on the left, there was a thickened tender tube, but the ovary was not felt. There were no bladder symptoms. Hot vaginal douches were ordered, and three weeks later, under ether, the uterus was dilated and curetted, with the hope of improving her condition before opening the abdomen. The operation was followed by marked relief of her symptoms for about two months. On July 18th she entered the Carney Hospital for the abdominal operation.

The patient was etherized by Dr. E. E. Everett; Dr. R. H. Morris was present. With the assistance of the late Dr. David P. Ronayne the abdomen was opened, and numerous adhesions found between the ovaries, tubes, and surrounding parts. A very long appendix was adherent, by its tip, and released. The right ovary contained a cyst as large as a hen's egg, and the left ovary a hematoma nearly as large as the cyst. The ovaries and tubes were tied off with silk quite close to the uterus and removed; the abdominal wound was closed with silkworm gut; the patient made a rapid recovery.

She began to menstruate soon after the operation, and continued to do so regularly and painlessly for about four months. The dyspareunia disappeared and her sexual appetite became normal. In May, 1899, she consulted me on account of morning sickness, nausea, cardialgia, and also abdominal enlargement, and was anxious to know whether she had a tumor. An examination showed clearly that she was pregnant. On September 12, 1899, she was delivered, after a natural labor, of a healthy girl, by Dr. Richard H. Morris, of Everett, Mass. About two or three weeks after confinement her baby died, and soon after that she menstruated, and has continued to do so regularly and normally since.

Among the cases previously published is one by Dr. George J. Englemann, formerly of St. Louis, now of Boston.[2] In this case pregnancy followed a double ovariotomy in which the right tube was left intact. A microscopic examination made of the specimen later showed that some ovarian tissue had been left.

Englemann also refers to a case of Professor Schatz, of Rostock,[3] who operated on February 20, 1880, and removed a large cystic tumor of the left ovary, including the outer third of the Fallopian tube, and all the ovarian tissue that could be found. The right ovary was diseased. "It was tied by means of three silk ligatures passed between it and the broad ligament, and was cut away in such a manner that a piece of ovarian tissue, at the most 2 millimetres broad, was left on the proximal side of the ligature; the right tube remained intact." This patient was delivered of a child May 12, 1885. The specimen had been preserved, and the cut surface of the right ovary "was found to contain ovarian tissue with Graafian follicles."

Dr. S. C. Gordon, Portland, Me., reports[4] 2 cases of pregnancy following removal of both ovaries and tubes. His first case seems to be a doubtful one, as there is not positive evidence that the ovaries and tubes were removed. Dr. J. R. Chadwick, who operated, had mislaid his notes, and could not say whether both ovaries were removed or not. The patient and her husband understood that they were.

Dr. R. Stansbury Sutton, of Pittsburg, Pa., re-

[1] Read before the Obstetrical Society of Boston, November 20, 1900.

[4] From Transactions of the American Gynecological Society, vol. xxi, p. 105, 1896.

ports a case of "double ovariotomy followed by pregnancy and delivery at term."[5]

Robertson[6] mentioned a case where he removed both ovaries, which were diseased, and the woman afterwards conceived and bore a child.

C. F. Harding[7] reports a pregnancy after ovariotomy.

Dr. A. Palmer Dudley[8] refers to a case of hysterectomy done by a German surgeon, who, leaving the ovaries and tubes, brought the latter down into the vagina, and the patient recovered. She became impregnated in the tubes, and carried the ovum six weeks. She then consulted him and he curetted the ovum from the tube dependent from the vault of the vagina, and on microscopical examination recognized the chorionic membrane and a portion of the fetus.

Kossman[9] reports a case of pregnancy and normal delivery, one and a half years ago, after removal of both ovaries. On November 12, 1895, he extirpated both ovaries in a woman who suffered from oöphoritis. The tubes were not removed. Vaginofixation completed the operation. About one and a half years later the husband reported his wife pregnant, which was verified at a subsequent examination. December 2d Kossman was summoned to the patient, but on arrival (two and a half hours after the beginning of labor) found her delivered of a living child. It must be surmised that particles of ovarian tissue were left behind which remained active. At the time of this report the patient is again pregnant.

In my own case it is to be regretted that the parts removed had not been subjected to a microscopic examination. It is remarkable that the woman, after the removal of both ovaries and both tubes and tying with silk, should become pregnant, and the only explanations that can be offered are those which have been used in other cases, which have appeared in literature. There may have been a third ovary, or a scrap of ovarian tissue must have been left behind.

Regarding supernumerary ovaries a few quotations will suffice. Garrigues,[10] quoting Biegel, says, "Supernumerary ovaries have been found 23 times in 500 bodies. In a case reported by Winckel there were three ovaries and three ovarian ligaments.[11] Regarding the passage of the ovum into the uterus, a ligature may have dropped off, leaving the stump of the tube open, or there may have been another ostium between the ligature and the uterus. In a case of mine, operated on seven years ago, there was a Fallopian tube with two ostia, each surrounded by fimbriæ. The condition escaped my notice at the time, and was afterwards pointed out to me by Dr. R. H. Fitz.

A STATE EPILEPTIC COLONY FOR ILLINOIS. — According to the *New York Medical Journal*, a colony for epileptics is to be opened, and Northcliff, near Elsah, Jersey County, has been conditionally accepted by the State Board of Charities as its future situation. Governor Tanner is reported to have stated on December 5th that there were more than 5,000 epileptics inmates of the various eleemosynary institutions of the State.

Medical Progress.

PROGRESS IN LARYNGOLOGY.

BY ALGERNON COOLIDGE, JR., M.D., BOSTON.

THE SPONTANEOUS ESCAPE OF CEREBROSPINAL FLUID FROM THE NOSE.

UNDER the heading of "nasal hydrorrhea," cases have from time to time been reported, varying so much in symptoms that a subdivision has been demanded. In some of these cases the watery flow is evidently a nasal secretion, in others examination has shown it to be of the same composition as cerebrospinal fluid, and an idiopathic escape of this fluid has been suspected.

St. Clair Thomson[1] has collected the published reports of 21 cases, of which 9 had undoubtedly an escape of cerebrospinal fluid, the others probably. To these he has added a case of his own, and taken the opportunity to go deeply into the subject. The escape of the fluid from the nose as a consequence of injury, although not frequently reported, has been established as a recognized possibility. Its spontaneous escape has not been commonly recognized. Our textbooks up to the present either do not mention it or group it indefinitely under the head of "nasal hydrorrhea." As a result of his study of these cases, Thomson concludes that the subarachnoid fluid can escape through the nose without trauma or new growth to explain how it effects an exit. The flow in most cases commences gradually, generally in middle life; it occurs in drops, and is continuous by day and night. It generally comes from one nostril only, but may come from both. It is clear and limpid, free from odor and only slightly salt. It may amount to about half a litre in twenty-four hours. The fluid is sterile, and answers all chemical tests of cerebrospinal fluid. There is in most cases a history of more or less headache, and occasionally other symptoms of disturbance of the nervous system. The common anatomical cause of this leakage has not yet been definitely determined. A simple solution of continuity in the base of the skull arising in some unknown manner may be the only explanation at present. Active treatment of these cases is more likely to do harm than good. It is, of course, very important that nothing should be done which might infect the nasal cavity, and any attempts to suddenly check the flow are to be avoided.

NASAL HYDRORRHEA.

Taking from this heading such cases as are due to an escape of cerebrospinal fluid, we have left such as exhibit a flow of watery fluid from the nose arising from the nasal mucous membrane. These cases of course run into others which are commonly classed as vasomotor rhinitis. Lermoyez[2] in an exhaustive paper reviewed by Waggett,[3] argues that spasmodic hydrorrhea is merely an accident of neuro-arthritism. Local lesions in the nose are not constant in these cases, while they may be purely secondary phenomena. Hyperesthetic spots often result from constant irritation, in the same way that polypoid hypertrophies are secondary lesions, and disappear on the ces-

[1] The Cerebro-Spinal Fluid, etc., by St. Clair Thomson, M.D., etc. London and New York: Cassell & Co., 1899.

[3] Journal of Laryngology, Rhinology and Otology, August, 1900.

sation of the hydrorrhea. The fluid is a true secretion and not a mere exosmosis, and is due to abnormal excitation of the secretory filaments of the superior maxillary nerve. The hyperemia and obstructive phenomena are the results of a true vasodilator activity. As a result of this explanation of its etiology it follows that he is opposed to local treatment. Although the galvanocautery and electrolysis will produce a temporary result by inhibiting secretion and vasodilatation, the literature of the subject shows that local treatment has produced few lasting cures, while cases are not infrequent in which over-zealous operating has done positive harm.

The arthritism itself cannot be cured; the author attacks the hypersecretion with atropine and the vasodilatation with strychnine. One dose of each is given daily for ten days at breakfast, two doses daily at meal times for the next ten days and occasionally three doses for a third ten days. Generally he gives a twenty-day course, and after a fortnight's rest repeats if necessary. He reports 15 cases treated by endonasal methods, with 2 cures, and 27 cases treated with atropine and strychnine, with a large proportion of cures.

THE INFLAMMATORY ORIGIN OF POLYPI.

In spite of many able monographs on the subject it it must be acknowledged that the etiology of nasal polypi has not yet been definitely determined. All arguments on this subject begin by quoting the theory of Woakes, that these growths are always due to a necrosing ethmoiditis, and by showing that this theory is wrong. The tendency, however, has been more and more to consider polypi always secondary to some previous inflammatory disturbance in the region of the ethmoid.

In "some critical and desultory remarks," Wright [4] argues that although bone disease or sinus disease is not infrequently the proximate cause of nasal polypi, yet neither of these conditions, nor both together, are sufficient to explain the proximate cause of every case of polypi. He is convinced that there is a class of cases, frequently associated with asthma and hay fever, in which a pure vasomotor neurosis is the important factor in the etiology. All these various factors may be at once present in varying degrees of importance. A vasomotor neurosis of the nasal blood vessels may exist without necessarily an accompanying asthma or hay fever, and thus become a factor in the etiology of nasal polypi.

THE NEGATIVE AIR DOUCHE FOR DIAGNOSIS OF DISEASE OF THE ACCESSORY SINUSES.

Seifert [5] and Réthi [6] have each described a method to aid in the diagnosis of disease of the accessory sinuses of the nose, especially empyema. Briefly, this method consists in applying a collapsed Politzer air bag to the nostril so as to make a negative air pressure in the nasal cavity, thereby drawing out enough secretion from the affected sinus to make its presence visible on inspection. Polypi must first be removed and all secretion wiped out. The nozzle of the air bag is then applied to the suspected side, both nostrils closed, and while the patient swallows to draw up the soft palate, the bag is allowed to suddenly expand. This may be repeated a few times, or iodide of potash may be given internally to make the secretion more fluid and larger in amount. This is often sufficient to prove the presence and locate the source of pus, taking the place of exploratory punctures or the removal of part of the middle turbinate, as is frequently done. This procedure may be useful, not only from a diagnostic, but also from a therapeutic standpoint if systematically used. Not only may headache and other discomforts of retention be relieved, but occasionally the secretion be permanently removed.

THE ADENOID FACE.

Since attention was first called to the importance of hypertrophy of the pharyngeal tonsil, and its removal became one of the most common of operations, both our textbooks and innumerable papers on the subject have didactically asserted that neglected adenoids or the consequent mouth breathing results in a faulty growth of the bones of the face. We have come to look upon the high arch, the crowded teeth, the narrow and high nasal cavities and the pinched or "rodent" facial expression, as *prima facie* evidence of past or present adenoid vegetations. During the past few years a few able papers have appeared, some of them founded on extensive clinical and anatomical investigation, which argue that we have been "putting the cart before the horse"; that narrow respiratory passages are no more likely to be filled with adenoids than the larger ones, but simply that when so filled the symptoms are more pronounced and the patient more likely to be brought for examination. We have already referred to Siebenmann's article.[7] Previously E. Fraenkel,[8] from careful measurements, and recently Grossheintz,[9] from a study of skulls, came to the same conclusions.

Wright [10] believes that while adenoids as the cause of narrow jaws has been a subject on which very erroneous views have been held, it is possible that the narrow jaw may have some etiological influence upon the occurrence of lymphoid hypertrophy in the pharyngeal vault.

OZENA.

This is a subject which has attracted an increasing amount of attention during recent years and still we are confronted with an increasing number of theories on its etiology and methods for its treatment. Grünwald's [11] conclusions point to a focal suppuration as the common or only cause. That the cause is to be sought in previous hypertrophy or purulent rhinitis or by the invasion of one or several forms of bacteria we have heard periodically for some years. The relation between ozena and the shape of the nasal cavities usually associated with it has received renewed attention by Meisser [12] and Gerber.[13] In brief, their conclusions are that ozena is the result of a lack of proper development of the nasal fossæ associated with retrograde metamorphosis of the mucous membrane.

Cozzotino,[14] in a long article, finds that ozena develops only in cases with nutritive deficiency. The first pathological change takes place in the periosteum and medullary space of the bone. Later the erectile tissue atrophies and then the glands. The epithelium is the last structure to become atrophic, showing that the disease is not secondary to catarrhal processes.

[14] Ann. del mal de l'or, July, 1899.

For the treatment of ozena the antitoxin injection of Belfanti and Della Vedova has not received wide endorsement. McBride[15] strongly advocates cupric electrolysis. Cleansing with alkaline solutions is taken for granted in all methods of treatment. Oil, tampons and vibratory massage are in common use, but by no means universally recommended. Of the local medicaments Knight[16] gives preference to menthol, formaldehyde, 1–5,000, ichthyol in a 2% to 5% solution, and gomenol, 2–5 parts in 1,000, all used in an atomizer.

BACTERIA IN THE HEALTHY NOSE.

Our knowledge of the bacteria of the healthy nose is summed up by Thomson.[17]

Considering the large quantity of dust and germ carrying air which passes into the nasal fossæ they are remarkably free from micro-organisms. Certain authors have always been able to find some organisms in the healthy nose, though always in small numbers; others have found none in the majority of cases. The difference is probably due to difference in technique. All have found that the vestibules swarm with organisms. Previous observers have demonstrated the action of the ciliated epithelium in sweeping out intruding matters, and the effect of the trickling of mucus in cleansing the mucous surfaces. Some claim decided bactericidal power for nasal mucus. The author, among others, has not been able to do more than prove that the mucus has an inhibitory effect on the development of micro-organisms, while some, again, simply believe that mucus is not a favorable medium for their development. The author reviews a recent monograph by Viollet,[18] who claims to have discovered that freedom of the nose from bacteria is due to leucocytosis and phagocytosis. To prove this he found it necessary to introduce carmine or microbes into the living nose, as the nasal mucus once removed did not show this phagocytic action. By introducing these substances into the nose he observed their absorption by the leucocytes of the nasal mucus. Among other bacteria he mentions the pneumococcus, the pneumobacillus and the bacillus of diphtheria. Thomson believes that there can be little doubt that phagocytosis plays its part in the nose as in other parts of the body, and shares in the work of removal.

ANOSMIA.

Onodi contributes a paper on this subject to the Thirteenth International Medical Congress.[19] Our knowledge of anosmia is extremely meagre, largely on account of the difficulty of combining anatomical and pathological study of cases. After a detailed description of the olfactory centres in the brain the author divides the clinical forms into essential or true anosmias, which may be either peripheral or central according to the part of the olfactory region affected, mechanical or respiratory anosmia and functional anosmia. Peripheral true anosmia may arise in connection with inflammation of the nasal mucous membrane as a result of influenza. This may be temporary or may result in atrophy of the nerve of smell. Syphilitic processes, chronic ethmoiditis, ozena or senile atrophy may produce the same results, though the latter is generally central in origin. Central true anosmia may be caused by cerebral tumors and other diseases of different parts of the brain, trauma, intoxication with tobacco, cocaine, mercury and other poisons, also by overstimulation and exhaustion of the sense of smell, also by the toxic influences of influenza and septic poisoning, and congenital defects of the olfactory centre. Tobacco and cocaine have also a peripheral action. Mechanical anosmia is caused by anything that interferes with nasal respiration. Functional anosmia is commonly due to hysteria, but various reflexes may produce it, as after ovariotomy, during menstruation, and after cauterization of inferior turbinates.

SUPRARENAL EXTRACT.

For two years the aqueous extract of the suprarenal gland has been widely used as a local vasoconstrictor especially for operative work in the nose. Its local effects are thus summarized by Swain:[20] It is a powerful local vasoconstrictor and contractor of erectile tissue. It can be used in considerable amounts without either local or general dangerous effects. It can be used any number of times without evil effect or danger of forming a habit. Its use seems to heighten the effect of any other drug used locally, notably cocaine. It is especially useful in acute congestion, but is also very helpful in certain chronic conditions of the hay fever type. Newcomb[21] describes its effects when injected into the veins of animals. There are produced extreme contraction of the arteries of peripheral origin, a remarkable and rapid rise in the blood pressure in spite of powerful cardiac inhibition, central vagus stimulation, and great acceleration and augmentation of contraction of the auricles and ventricles, especially the former, after section of the vagi. Respiration is only slightly affected, becoming more shallow. A more recent paper by Hopkins[22] after the extract had been in common use for some months, brought out an interesting discussion. The writer and most of those who took part in the discussion had become convinced that the use of the extract at the time of operation was followed by a tendency to secondary hemorrhage. Some operators packed the nose after operating, diminishing the danger from bleeding. For tonsils and adenoids this secondary bleeding is more serious, as it is much more difficult to control. As a styptic in bleeding from other causes this extract was found of good service. Its use in acute coryza is uncertain. In some cases an intense, painful rhinitis has followed the use both of the dry extract and of the aqueous solution inhaled or sprayed into the nose.

THE FRENUM OF THE UPPER LIP.

B. Fraenkel[23] in the case of three children brought to him with the question of adenoid vegetations because they held their mouths habitually open found that this was caused by a short frenum of the upper lip. There was no other anatomical peculiarity about the mouth, nor obstruction to breathing. After section of this frenum there was no difficulty in keeping the mouth closed. This point might easily be overlooked. The section of the contracted frenum offers even less difficulty than cutting the frenum of the

tongue, as there are no blood vessels of any size in the neighborhood.

THE PREVENTION OF RECURRENCE OF PERITONSILLAR ABSCESS.

Botey [24] argues that peritonsillar abscess arises from sepsis spreading from a tonsillar crypt to the supratonsillar fossa and that to prevent recurrence the latter must be left freely and widely open. This can only be accomplished by complete removal of the upper half of the tonsil. The fossa, which is more than a centimetre in depth, often has its orifice closed by adhesions. The tonsil is frequently adherent to the pillars, the plica, the margo semilunaris and to the walls of the fossa. When not too adherent the tonsil may be cocainized and the upper portion pulled forward and removed with a knife or snare sufficiently to free the fossa. When the adhesions are extensive and the tonsil small it is often difficult and tedious or impossible to do this. In such cases the author makes two incisions between the tonsil and the anterior and posterior pillars extending well up into the soft palate, and after drawing the tonsil out, another incision joining the two above the tonsil, which is then removed with scissors.

THE CADAVERIC POSITION OF THE VOCAL CORDS.

A certain position of the vocal cords, called the cadaveric position, has for long been commonly supposed to be the position in which the cords are found in the cadaver. Fein,[25] in a paper of forty pages, describes his exhaustive investigations on the position of the vocal cords in the cadaver. He finds that the vocal cords immediately after death are in the median line, or very near it. The result of rigor mortis is to draw the cords away from the middle line, so that the glottis broadens. The width of the glottis in the undisturbed body is different from what it is after the larynx has been taken out, and becomes so as soon as it is taken out. After removal of the larynx the cords are found in a position half way between extreme abduction and adduction. After rigor mortis has passed the cords remain between abduction and adduction, but tend to return towards the median line. There is no typical form of the cadaveric glottis; it is as variable as it is during life. After complete cessation of rigor mortis the thickness of the cords appears to increase. At the moment of death all forces in the body suddenly cease, and the arytenoids sink backwards, which tends to approximate the cords. At the onset of rigor mortis the abductor muscles stiffen first and the glottis begins to open.

THE MECHANISM OF COUGHING.

The question of the mechanism of the sudden opening of the glottis in connection with coughing has been studied by Valentin.[26] The larynx of a dog was examined through the mouth, and it was seen that in coughing the mechanism was similar to that in man. The glottis was closed and after the tension of the air in the lungs had been raised by compression of the thoracic walls, the cords were suddenly widely abducted. The trachea was then divided just below the larynx, in such a way that the glottis could be seen from below. Coughing was then induced by tickling different points both in the trachea and bronchi and in the larynx. In each case the cough began by an expulsion of air from the lower section. After this expulsion of air had begun, sometimes half a second or a second later, there was seen a sudden violent symmetrical abduction of the vocal cords, which lasted only a moment and was followed by a short adduction and the normal position of the cords. This proves that the abduction is caused not by any air pressure from below, but by a reflex contraction of the postici independent of the tension of the air and arising at an interval after the contraction of the chest wall. The whole act of coughing is aroused as a reflex by irritation of one of many parts of the respiratory tract. Repeated irritation of any one spot finally fails to produce this reflex.

Reports of Societies.

THE OBSTETRICAL SOCIETY OF BOSTON.

MALCOLM STORER, M.D., SECRETARY.

MEETING of November 20, 1900, the president, DR. ALFRED WORCESTER, in the chair.

DR. M. A. MORRIS, by invitation, reported

PREGNANCY FOLLOWING THE REMOVAL OF BOTH OVARIES.[1]

DR. F. H. DAVENPORT: While I have never had a case quite similar to the one Dr. Morris has reported, I would like to refer to one in which I removed by the abdomen the uterus and both ovaries and tubes, yet she menstruated for seven months.

DR. W. F. WHITNEY: There is only one really authenticated case in which an accessory ovary had a distinct ligament of its own. Probably all the others were cases in which parts of the ovary were cut off by adhesions or other causes. The fact that more or less ovarian tissue is often left behind in amputations of the ovary is emphasized by the many cases brought to me in which the ovary shows a cut surface. The striking fact in Dr. Morris's case is that she got pregnant after the tube was tied off. In a case like this it is more plausible to assume that the ligature slipped and that some fragments of ovary were left behind than to think that there was a complete third ovary and tube.

Dr. Whitney then showed a specimen of tube with accessory ostium.

DR. E. REYNOLDS: I do not think it necessary to assume that the ligature slipped. Tubes are very apt to grow patent, and this explains many cases of peritonitis recurring after operations for tubal disease. I now always excise the tube at the uterine cornu, and since doing this I am certain that I have seen less recurrent trouble.

DR. F. A. HIGGINS: I am reminded of a case in which I left both ovaries, but removed both tubes, tying off with catgut. She became pregnant after a time. I suppose when the catgut was absorbed the tube became patent again.

DR. EDWARD REYNOLDS reported a case of

VESICAL IMPLANTATION OF THE URETER BY DUDLEY'S FORCEPS METHOD AFTER THE FAILURE OF SEVERAL PLASTICS.[2]

[1] See page 86 of the Journal.
[2] See page 84 of the Journal.

DR. M. H. RICHARDSON reported

A CASE OF OBLITERATION OF THE RIGHT URETER BY A CALCIFIED FIBROID; REMOVAL OF FIBROID AND IMPLANTATION OF THE URETER INTO THE BLADDER; RECOVERY.[8]

DR. REYNOLDS: This case brings out the fact which I perhaps did not insist upon sufficiently in my paper, that the most favorable elements for success in the implantation of a ureter are that you can get plenty of end to the ureter and also that you can make the end of the ureter reach the bladder without too much tension. In such a case as Dr. Richardson's I probably would prefer the end-to-end anastomosis, but where the conditions I have referred to cannot be reached I would prefer the Dudley operation.

DR. G. H. WASHBURN showed the specimen from a case of

EXTRA-UTERINE PREGNANCY.

The woman, age thirty-three, had always been regular till two months ago, when she went ten days over time. Since then she has had a somewhat irregular flow with two attacks of severe pain, but no faintness. When seen ten days ago there was a mass behind the uterus which Dr. Washburn diagnosed as an extra-uterine pregnancy of nine weeks' growth. Two days ago there was another attack of pain. Operation this morning showed a large tube in the cul-de-sac still unruptured and tied down by fresh adhesions. A report on this enlarged tube will be made at the next meeting.

REGISTRATION OF MIDWIVES.

DR. J. G. BLAKE spoke of the deplorable amount of puerperal sepsis among the poorer Italians of this city, all of which could be traced to the midwives whom the Italians prefer to employ. Many of these women are ignorant and filthy to a degree, and the suggestion was made that steps be taken looking towards the registration and proper instruction of them.

On motion of DR. REYNOLDS a committee of three was appointed to investigate the matter and report at a later date.

DR. WORCESTER reported briefly a case of

RAPIDLY PROGRESSIVE CARDIAC DISEASE COMPLICATING PREGNANCY.

THE AMERICAN PHYSIOLOGICAL SOCIETY.

THIRTEENTH ANNUAL MEETING, HELD IN THE PHYSIOLOGICAL LABORATORY OF JOHNS HOPKINS UNIVERSITY, BALTIMORE, MD., DECEMBER 27 AND 28, 1900.

FIRST DAY.

AFTER the transaction of general business, papers were read, abstracts of which follow.

OBSERVATIONS ON THE BLOOD PRESSURE DURING THE PERIOD OF NORMAL SLEEP.

This paper was read by DR. W. H. HOWELL, for DRS. BRUSH and FAYERWEATHER. Many difficulties have to be overcome in the arrangement of apparatus suitable for recording blood pressure during sleep, the ordinary types of plethysmograph and sphygmograph being inadequate for this purpose. The apparatus used in these experiments was a combination of these two instruments which could be applied to the radial artery, and with which three very perfect records, covering the entire period of normal sleep, were obtained.

These records show that the time when blood pressure is lowest is coincident with the time when sleep is deepest, namely, about one and a half hours after going to sleep. From that time until the time of waking there is a gradual rise in blood pressure, indicating a gradual vasoconstriction. These results confirm the observations made by Professor Howell with the plethysmograph more than three years ago.

Among the minor points of the records is to be noted a marked difference in blood pressure corresponding to the sitting posture and that corresponding to the lying posture, this difference being shown when the subject lay down at night and when he arose in the morning. The explanation of this phenomenon rests, in great part at least, on hydrostatic grounds.

There is only a comparatively slight fall of pressure (4 millimetres of mercury) during the short space of time when sleep actually supervenes. This is explained by the fact that towards night there is a gradual loss of tone in the blood vessels, and that physiologically the subject is already partially asleep.

These observations are in harmony with the vasomotor theory of sleep, and indicate that the phenomena of sleep and waking are accompanied by gradual rather than sudden changes of vasomotor tone.

THE EFFECT OF CO_2 AND O_2 ON SMOOTH MUSCLE.

DR. A. M. CLEGHORN read this paper by title.

DR. S. J. MELTZER read a paper

ON THE MOVEMENTS OF THE ESOPHAGUS AND THE CARDIA AND ON SOME OF THE COMPLEXITIES OF THE CENTRE OF DEGLUTITION.

Dr. Meltzer has by a new series of experiments again proved the theory of Mosso, Kronecker and Meltzer, that the main act of deglutition is the result of a series of reflex acts, only one centripetal impulse being necessary to bring about all movements. In a second series, he shows that for the esophagus and cardia there are local reflexes, and that this section has its own afferent and efferent impulses. The general reflexes differ from the local in that anesthesia easily paralyzes the centres for the contraction of the esophagus, while contraction of the cardia is as resistent to paralysis as is the first act of deglutition.

The local reflexes, on the other hand, he proved to be more resistant to anesthesia and debilitating factors even in the first act of deglutition as well as later. They are also complicated by inhibiting impulses. The local reflexes can be brought out by injection of salt solution or even air in amounts of not less than 1 cubic centimetre. The downward direction of peristalsis remains the same even when the air or salt solution is introduced from the cardia upwards.

A STUDY OF THE SEASONAL VARIATIONS OF GROWTH IN WEIGHT OF CHILDREN.

This paper by DRS. G. W. FITZ and F. W. HUTCHINGS was read by title.

[8] See page 83 of the Journal.

SOME NEW OBSERVATIONS ON BLOOD PLATES AND LEUCOCYTES.

DR. G. T. KEMP and MISS HENRIETTA CALHOUN presented this paper.

In the enumeration of blood plates some difficulty is encountered from the fact that when the ordinary dilating fluids, such as physiological salt solution or Hayem's fluid, are used, the plates come together, forming almost unrecognizable masses. This disadvantage may be overcome by the use of a fluid devised by these observers, consisting of a 2.5% solution of formaldehyde tinged with methyl green. With the aid of this fluid and as the result of a large number of observations, a fairly constant ratio has been found to exist between the blood plates and the red corpuscles, namely 1–5.8. This observation agrees with Hayem's theory that the blood plates are young red corpuscles. It is also found that the blood plates do not contain hemoglobin.

The influence of the leucocytes on blood coagulation was also studied. By preparing slides at freezing temperature and allowing them to warm gradually while under observation, it is found that during coagulation there is no progressive change or breaking down of the leucocytes. This is in direct opposition to the assertions of Lilienfeld that the leucocytes are broken down in coagulation to furnish the so-called thrombin, and that the nodes from which the fibrin filaments radiate are merely broken down leucocytes. On the contrary, Dr. Kemp finds that the fibrin threads radiate from masses of disintegrated blood plates, which, unless appropriately stained, appear so nearly like broken down leucocytes as to account for the error which he claims Lilienfeld to have made. In his opinion, therefore, the blood plates rather than the leucocytes are the responsible factors in blood coagulation.

ON THE RATE OF FATIGUE OF NERVE CENTRES.

DR. R. S. WOODWORTH (by invitation) read this paper.

The observation that many of the motor functions may be repeated consecutively for from 2,000 to 10,000 times without loss of accuracy has led Dr. Woodworth to a study of the rate of fatigue of nerve centres, with the idea that this rate is at present overestimated.

By measuring the voluntary contractions of the finger with Mosso's ergograph, he finds that when he allows a complete relaxation to take place after each contraction, the rate of fatigue is very much slower than has hitherto been observed; the relaxation apparently doing away with fatigue as efficiently as a long rest. He concludes that the comparatively rapid rate of fatigue, which up to this time has been considered to be the true one, is due to the fact that there was no complete relaxation, and consequently the factor of muscle fatigue has been introduced.

Exactly similar results have been obtained when the frog's gastrocnemius muscle is stimulated reflexly or by excitation of the proper portion of the spinal cord. Experiments on some of the simpler mental functions, such as the memorization of columns of figures, have led to the same conclusions.

These results possess the negative value of showing that the curves previously published can be applied only to muscular fatigue, and that deductions therefrom with regard to the rate of fatigue of nerve centres are unreliable.

DR. E. T. REICHERT showed a

STUDENT'S LABORATORY TABLE.

After emphasizing the desirability of increased facilities for students' work in the physiological laboratory, Professor Reichert presented plans and photographs of a student's table which embodied the following improvements:

An upright glass case built into the table provides a place for all the apparatus needed by the student throughout the course. By this means the wear and tear incident to the carrying of delicate apparatus back and forth many times from the storage room is avoided. Two countershafts for the transmission of the power are provided for each table, one at each end, thus enabling two drums to be revolved at different rates of speed.

A RHEOCHORD.

DR. E. T. REICHERT showed this instrument, which is in reality a monochord, consisting essentially of a cylindrical rubber core, the surface of which is cut into a deep continuous spiral groove. The resistance wire is wound about the core in this groove. An endless screw underneath the core and geared to it by series of cogs bears the brass contact point which plays in the groove against the wire. By simple rotation of the core on its axis, the distance from the end of the resistance wire to the contact point is diminished or increased. This modification thus provides a means of producing a gradual and uniform variation in the amount of resistance introduced into a circuit.

A RHEONOME.

This was also shown by DR. E. T. REICHERT, and presents this advantage: the metal bar which is ordinarily used to transmit the current, and along which the movable binding post slides, is here replaced by a hard-rubber trough filled with acidulated water. By this device the extent of possible variations in the strength of the electric current may be very greatly increased.

A RHEOCHORD.

DR. G. P. CLARK presented this instrument. It was designed by Professor Clark and consists of a metre stick joined to a circular wooden base. The resistance wire extends along the side of the metre stick and may be connected by appropriate plugs with any one or all of a number of resistance coils concealed in the base. The "slider" may be easily moved along the metre stick. This apparatus possesses the advantages of being easily and cheaply made, and of furnishing resistance which can be quickly varied and accurately measured.

A HAIR CAST OF A LIVING HUMAN STOMACH.

DR. G. P. CLARK read this paper for DR. NATHAN JACOBSON. This cast, exhibited by Professor Clark, was taken from the stomach of a girl ten or twelve years of age. The habit of chewing the ends of her braids gave rise to this deposit, which completely filled the stomach and which LOW shows its exact contour. The cardiac end is much softer than the py-

loric and shows evidence of the relative strength and activity of the muscles of those portions of the stomach walls.

(To be continued.)

Recent Literature.

The Thirty-Second Annual Report of the Secretary of State on the Registration of Births, Deaths, Marriages and Divorces in Michigan for the year 1898. Edited by CRESSY L. WILBUR, M.D., Chief of Division of Vital Statistics. Lansing, Mich. 1900.

This report for the year 1898 marks a new era in the history of registration in Michigan, and is virtually the first in a new series of more reliable vital statistics for that State, since it is the result of new legislation enacted in 1897, whereby the registration returns of the State have been very greatly improved, and are now much more complete than those of any previous year.

Under the new law a certificate of death is required, and must be presented to the local registrar in every case of death before burial is permitted. Under the old law, the statistics of deaths were collected once a year, at the time of taking the annual assessment, and it was estimated that only 60% of the deaths were thus obtained.

The birth registration appears to be still quite defective, the compiler stating that "probably not over two-thirds of the births that actually occur in the State each year finally get upon the records."

The Bertillon classification of the causes of death is fully presented in an appendix, and has also been adopted in a modified form as the basis of classification in the report. This system has received the sanction of the American Public Health Association, as well as of very many foreign sanitary authorities, and is now quite generally adopted by most of the States in which registration returns are collected.

In addition to the publication of the annual report the compiler has issued during the past two years a monthly bulletin of the vital statistics of Michigan, which has not only proved helpful to the registrars in that State, but has been a public educator upon the general subject of vital statistics.

Much credit is due to Dr. C. L. Wilbur, who may very properly be styled the registrar-general of Michigan, since his duties are quite similar to the English official bearing that title. Dr. Wilbur has accomplished very much toward bringing the State of Michigan into line, as one of the foremost registration States of the Union.

A Clinical Treatise on Fractures. By WILLIAM BARTON HOPKINS, M.D., Surgeon to the Pennsylvania Hospital and to the Orthopedic Hospital and Infirmary for Nervous Diseases. Philadelphia: J. B. Lippincott Co. 1900.

This octavo of 264 pages on a heavy calendered paper is "a report of the unpublished clinical lectures delivered by the author at the Pennsylvania Hospital." The author has purposely omitted many of the details of treatment which would ordinarily be given in clinical lectures and has omitted historical matter which, as he states, "is inseparable from a work of reference," but "is not essential in a treatise intended for practical use." The author describes clearly, in each instance, a simple and effective method of treatment, which, in many instances, is not the commonly accepted method, yet it is a record of his clinical experience and as such is of value. The illustrations and skiagrams are excellent and the book is a safe guide to the treatment of fractures.

The chapter on compound fractures is judicious, and, we are glad to say, goes into the detail of the treatment in an admirable manner. The section on bone joining, in which the author selects the word joining "on account of its technical significance in the arts as applied to wood or metal," is of a good deal of interest. Various illustrations are used to show a scarf joint formed experimentally by the author.

There is not in the book the information given as to prognosis that would seem desirable and which would naturally be looked for in a clinical treatise on fractures. The prognosis of injuries of this description is not any too well known and in a future edition of this work we trust the author will give some attention to this important part of the consideration of fractures.

Atlas and Epitome of Diseases Caused by Accidents. By DR. ED. GOLEBIEWSKI, of Berlin. Authorized Translation from the German, with Editorial Notes and Additions by PEARCE BAILEY, M.D., Consulting Neurologist to St. Luke's Hospital and the Orthopedic Hospital, New York, and to St. John's Hospital, Yonkers; Assistant in Neurology, Columbia University; Author of "Accidents and Injury; Their Relation to Diseases of the Nervous System." Forty colored plates, and 143 illustrations in black. Philadelphia: W. B. Saunders & Co. 1900.

This authorized translation from the German by Dr. Pearce Bailey of Dr. Golebiewski's work is of a good deal of interest. The German State Insurance Bureau has published a table of accidents for statistical purposes for the use of all the trades unions, and what is of especial interest is that the amount of indemnity is graded in accordance with the disability. In cases of total disability the full amount is paid; when the disability is partial, only a part of the amount. From this, suggestive and interesting statistics have been made up.

The book is divided into two parts, one treating of injuries in general, the other of injuries affecting special structures and regions of the body. It is profusely illustrated with colored plates, most of which are drawn from life. The text, the author states, is based on an experience with accident cases extending over thirteen years, embracing a total of 5,245 cases, many of which have remained under observation since the first few years following the passage of the Accident-Insurance Law.

It is a book that every one who has to do with the legal side of accident cases should possess.

Suggestions to Medical Writers. By GEORGE M. GOULD, A.M., M.D. Philadelphia: The Philadelphia Medical Publishing Co. 1900.

Dr. Gould has republished in book form the various bits of suggestion and advice to writers which have become familiar to readers of the *Philadelphia Medical Journal.* Much of the advice is good, some of it is unnecessary and some of it, we confess, seems to us bad. We have, for example, little sympathy with the

attempted reformed spelling, which Dr. Gould has striven to introduce. It appears to us, also, a labor lost to attempt to influence style by writing about it, nor can we reconcile in a chapter devoted to the improvement of style such phrases as the following: "Strabismic construction" and "sentences that suffer from spastic paraplegia." To those who have their own ideas of writing English, much of the advice is superfluous, and to those who have not we fear that a perusal of this book would simply make a bad matter worse. The erudition of the author is, however, abundantly manifested on almost every page, and as an epitome of useful information we can commend the book much more conscientiously than as a safe guide for the inexperienced medical writer. A valuable chapter on the History and Psychology of Words is appended.

The Pathology and Surgical Treatment of Tumors. By N. SENN, M.D., Ph.D., LL.D., Professor of Surgery, Rush Medical College, in affiliation with the University of Chicago; Professor of Surgery, Chicago Polyclinic; Attending Surgeon to Presbyterian Hospital; Surgeon in Chief, St. Joseph's Hospital, Chicago. Second edition, revised. Illustrated by 478 engravings and 12 full-page plates in colors. Philadelphia: W. B. Saunders & Co. 1900.

"The text of the first edition of this book has been carefully revised and many additions have been made. A new section has been added on Sarcoma of the Decidua. Many of the old illustrations have been eliminated, and are replaced by others intended to explain more satisfactorily the subjects they represent. Most of the new illustrations are original."

The book is unquestionably the best work on tumors and is extremely useful to the surgeon as a book of reference. It is arranged systematically, the material is presented in an attractive way and it is filled with practical details. Operations are described in full detail and the status of a given subject is judiciously presented. The work is but another proof of Dr. Senn's extraordinary industry and is one of his best pieces of work.

A Manual of Surgical Treatment. By W. WATSON CHEYNE, M.B. F.R.C.S, F.R.S., Professor of Surgery in King's College Hospital and the Children's Hospital, Paddington Green, etc., and F. F. BURGHARD, M.D. and M.S. (Lond.), F.R.C.S., Teacher of Practical Surgery in King's College Hospital and the Children's Hospital, Paddington Green, etc. In seven volumes. Vol. IV, The Treatment of the Surgical Affections of the Joints (including Excisions) and the Spine. Philadelphia and New York: Lea Brothers & Co. 1901.

Volume IV of this work is in many respects more satisfactory than its predecessors. The authors disarm criticism when they say they "would desire once more to reiterate the fact that the object we originally set before ourselves was to describe as fully as possible only those methods of treatment which have proved most efficient in our hands. To this plan we have adhered; and therein also will be found our justification for the omission of certain newly introduced methods of treatment which may prove of great value, but which are as yet too recent to enable a definite verdict to be pronounced upon them."

The volume deals with the treatment of surgical affections of the joints, including excisions and the spine. It certainly presents the detail of many of the generally accepted methods of treatment, but is still in many respects antiquated.

The chapters on the treatment of the nervous affections of the joints and on rheumatoid arthritis are admirable. The chapter on scoliosis is fairly good, but does not represent modern treatment. The appendix upon medical gymnastics is taken from Dr. Percy Lewis's book on "The Relief and Cure of Spinal Curvature."

The scope of this "Manual of Surgical Treatment" appeals to us so strongly that perhaps we expect more from it than we have any right to. Certainly the views of the authors are presented and the value of methods of treatment clearly set forth. This is what they undertook to do and they certainly are accomplishing their purpose.

Diseases of the Gall Bladder and Bile Ducts, Including Gall Stones. By A. W. MAYO ROBSON, F.R.C.S., Senior Surgeon to the General Infirmary at Leeds; Emeritus Professor of Surgery in the Yorkshire College of the Victoria University; Member of Council and Hunterian Professor of Surgery and Pathology at the Royal College of Surgeons of England. Assisted by FARQUHAR MACRAE, M.B., C.M. (Glas.). Second edition. New York: William Wood & Co. 1900.

This is the second edition of Dr. Robson's Hunterian Lectures. He has recast the whole book and has changed it from the lecture to the narrative form. He has added two new chapters on Membranous Cholecystitis and Gall Stones. An index and a table of contents with some new illustrations complete the work. The book now constitutes an excellent guide to gall bladder and bile duct surgery.

The book is divided into the following chapters: Anatomical Considerations, Inflammatory Affections, Intestinal Obstruction, Tumors of the Gall Bladder and Bile Ducts and Gall Stones, or Cholelithiasis. The nomenclature of affections of the gall bladder and bile ducts is in great confusion and there is need of a new classification of the subject. We trust that in a future edition of this most excellent work Dr. Robson will undertake this labor. The work bristles with practical points and if an intelligent classification of the affections of the gall bladder and bile ducts could be made, it would add greatly to the value of the book. There is an extensive list of case histories which are of value in illustrating various important points.

Appendicitis and its Surgical Treatment. With a Report of 185 Operated Cases. By HERMAN MYNTER, M.D. (Copenhagen), Professor of Clinical Surgery in University of Buffalo, Buffalo, N. Y. Third revised edition. Philadelphia and London: J. B. Lippincott Co. 1900.

This is an octavo volume of 220 pages, and is the third edition of this work. The author, desiring to obtain the degree of Doctor of Medicine from his Alma Mater, the University of Copenhagen, twenty-six years after graduation, submitted this monograph to the University, and it was accepted in July, 1897. All through the work one sees evidences of a "labor of love" and the thoroughness with which the author has gone into the subject is worthy of high commendation. While all would not agree with the writer in the de-

ductions which he draws from the facts that are at his disposal, yet one cannot but believe that the book is a most excellent contribution to our knowledge of this very important subject. It is a book that any one desiring a complete knowledge of the subject would turn to in research work on appendicitis.

Therapeutics: Its Principles and Practice. By HORATIO C. WOOD, M.D., LL.D. (Lafayette, Yale), Professor of Materia Medica and Therapeutics and Clinical Professor of Diseases of the Nervous System in the University of Pennsylvania; Member of the National Academy of Science. Eleventh edition, remodelled and in greater part rewritten. By HORATIO C. WOOD, M.D., and HORATIO C. WOOD, JR., M.D., Demonstrator of Pharmacodynamics in the University of Pennsylvania. Philadelphia and London: J. B. Lippincott Co. 1900.

The eleventh edition of this work marks the completion of a quarter of a century since it first made its appearance. This fact alone is a sufficient guarantee of its excellence. But what most attracts our notice is the energy displayed by the authors in the revision which the text has undergone. It truly has been "rewritten." The reader will here find described all the important newer remedies; at the same time he will be gratified that the book has not been increased in bulk, for unessentials have been omitted.

A Guide to the Instruments and Appliances Required in Various Operations. By A. W. MAYO ROBSON, F.R.C.S., Senior Surgeon to the Leeds General Infirmary; Hon. Consulting Surgeon to the Keighley and Batley Hospitals; Emeritus Professor of Surgery in the Yorkshire College of the Victoria University; Member of Council and Hunterian Professor R. C. S. of England. Second edition. London, Paris, New York and Melbourne: Cassell & Co., Ltd. 1900.

This is the second edition of this little handbook, which was designed by the author for his house surgeons and dressers at the hospital. It gives excellent lists of instruments to be laid out for a given operation, although some of the names of instruments are not familiar to an American. To a student it should be valuable in that it reviews for him the instruments that would be necessary to prepare for a given piece of operative work.

A Text-Book of Practical Therapeutics. With Especial Reference to the Application of Remedial Measures to Disease and their Employment upon a Rational Basis. By HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. With special chapters by DRS. EDWARD MARTIN, G. E. DE SCHWEINITZ and BARTON C. HIRST. New (eighth) edition. In one octavo volume of 796 pages, with 37 engravings and 3 colored plates. Philadelphia and New York: Lea Brothers and Co.

The first edition of this book was good, but the last edition is an improvement on all the others. It is chiefly notable because it has been brought so thoroughly up to date. The volume is not perfect; defects which should be remedied in another edition could still be pointed out, but it is so much better than many other works of a similar character that it deserves our commendation.

The Thompson Yates Laboratories Report. Edited by RUBERT BOYCE and C. S. SHERRINGTON, with illustrations and plates. Volume I, Reprints 1898–1899. Volume II, Reprints and Reports 1898–1899. Liverpool: University Press. 1900.

These two elaborate volumes, of 237 and 264 pages respectively, and with numerous beautifully executed plates, are the first instalments of the published work of the Thompson Yates Laboratories. The first volume contains an account of the opening of the laboratories in 1898 by Lord Lister, accompanied by Professor Virchow, and also an elaborate series of papers by Sherrington and others on various matters connected with the nervous system. The second volume gives in detail several researches of much practical interest and importance, among which may be mentioned an investigation on "oysters and disease" and another on malaria. The presswork and illustrations leave nothing to be desired; we shall await succeeding issues of the reports with interest and confidence that they will sustain the very high standard set by these first publications.

Uric Acid as a Factor in the Causation of Disease. A Contribution to the Pathology of High Blood Pressure, etc. By ALEXANDER HAIG, M.A., M.D. (Oxon.), F.R.C.P. Fifth edition, with 75 illustrations. Philadelphia: P. Blakiston's Son & Co. 1900.

Few medical books are more familiar than this. The theories and facts set forth have excited attention, leading to a fifth edition of the work, expanded to the length of 846 pages. The author is more confident than ever of the correctness of his theories, and adduces many new facts to bear them out. The general scope of the book remains unchanged.

Speech-Hesitation. By E. J. ELLERY THORPE. New York: Edgar S. Werner Publishing and Supply Co. 1900.

This small book of 75 pages is a practical record of the author's experience as a teacher in correcting certain defects of speech. It is written in a simple, straightforward way and ample use is made of actual cases for illustration. We are not prepared to say whether the method advised will do all that is claimed for it, but it is certainly worthy of careful trial. We recommend the book to those interested in voice training as an intelligent and valuable presentation of a highly complex subject.

The Surgical Treatment of Congenital and Pathological Disfigurements of the Face. Abstract of the Mütter Lectures of the College of Physicians of Philadelphia, for 1900. By JOHN B. ROBERTS, A.M., M.D., Professor of Surgery in the Philadelphia Polyclinic; Surgeon to the Methodist Hospital. Philadelphia: The Philadelphia Medical Publishing Co. 1900.

This is an abstract of the Mütter Lectures on this subject and is reprinted from the *Philadelphia Medical Journal.* The important subject of cosmetic surgery has not received the attention that it should. The writer gives a very interesting presentation of the subject, but the subject matter is worthy of better paper, printing and binding. Perhaps the author will expand these Mütter Lectures and will dignify the book by going more minutely into the detail of plastic work.

THE BOSTON
Medical and Surgical Journal

THURSDAY, JANUARY 24, 1901

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE THIRTY-FIRST ANNUAL REPORT OF THE STATE BOARD OF HEALTH OF MASSACHUSETTS.

IN its report for the year 1899 the State Board of Health records a diminishing death rate in recent years, which is especially gratifying in the group of destructive infectious diseases and marked enough in them to much more than counterbalance the increased fatality of those classified as local diseases (of the brain, heart, lungs, kidneys), although in 1899 the rates from diphtheria, scarlet fever, measles and pneumonia were higher than in 1898, and the unusually large number of 105 cases of smallpox were reported, with 14 deaths. The total death rates in 1897, 1898 and 1899 were respectively for the State 18.1, 17.5 and 17.4 per 1,000 living, as compared with an average of 19.5 for a long period of years.

No case of smallpox occurred in any town in which rags were used for the manufacture of paper. The usual investigations of the board showed that there had been such gross violations of the laws regarding vaccination and such carelessness as to revaccinations that the laws regarding smallpox are given in full.

The reduction in the typhoid fever rate per 10,000 living has been from 8.2 in the five years 1871–1875 to 2.6 at present, and chiefly through the introduction of pure water supplies, the most notable improvement having been in Lawrence, from 11.2 in 1886–1890 to 2.5 in 1896–1899. But it is still, in general, too large.

In diphtheria there has been a steady decline in the mortality since 1894 excepting a rise in 1899 over 1898.

In the town of Brookline and in 10 of the 33 cities in the State there were hospitals for the treatment of infectious diseases, and in 22 cities provision was made in some sort of separate structure for the reception of persons suffering with smallpox, whereas the statutes provide that there shall be accommodations in every city of the State for the treatment of infectious diseases, if the local board of health demands it. In another respect also there is room for improvement in our public health service and we find that Governor Crane repeats the recommendation of the board in the following words:

"The smaller towns to the number of 150 or more are without organized health boards, and a decided advance might be made if measures could be taken for combining these towns into sanitary districts large enough to justify the employment of competent sanitary inspectors."

The high death rate reported from cancer, which has nearly trebled in about forty years, although in large part due to more accurate diagnosis and improved registration, has led the board to make a special investigation into the matter, to be reported later.

The advice given to cities and towns has grown to be of such magnitude and importance that its record occupies 120 pages of the report, all of which should be studied with care by every local board of health in the State which has to do with the problems of supplying pure water and providing decent drainage in their several localities, and the board's 11 pages of rules and regulations for preserving the purity of water supplies mark the great advances made in recent years, under the board's wise direction, in legislation and in sanitary control.

The systematic examination of water supplies of the State, begun in 1887, has been continued and reported upon from year to year. That and the examination of rivers; a summary of water supply statistics, including records of rainfall and flow of streams; experiments upon the purification of sewage and water at the Lawrence Experiment Station; the occurrence of iron in ground waters, and experiments upon methods of removal, and the purification of the sewage in the cities and towns in Massachusetts, altogether constitute a record of original work of 450 pages, which, with the board's previous reports upon these subjects, are of the first importance and authority.

Under the laws regarding food and drug inspection, there were examined during the year 6,186 samples of milk, with 1,680 found below standard; 3,069 samples of other kinds of food, with 454 below standard, and 547 of drugs, with 244 found adulterated. There were 47 complaints made by the board in the courts for violation of the statutes in these respects, with 45 convictions.

From the report upon the production, distribution and use of diphtheria antitoxin it appears that 31,997 bottles of antitoxin were distributed during the year to local boards of health, to contagious disease hospitals and to physicians. Examinations for diagnosis were made in 2,581 cases, of which 2,256 proved to be diphtheria. The board notes an increase in the dose of antitoxin used and remarks that expressions of doubt as to its efficacy are now rarely heard. An interesting table is given of cases of long persistence of diphtheria bacilli in the throats of patients convalescent from diphtheria.

There were 571 specimens examined for the bacilli of tuberculosis, and 76 suspected of containing malaria parasites.

Under the headings of statistical summaries, of disease and mortality, of health of towns and of inspection of summer resorts a mass of material of more than local interest is collected.

If our registration reports of births, marriages and deaths could be again placed under the competent direction of the board, where they belong, and if these reports could be raised from their present position to the high standard of our health reports, it would be well worth the united efforts of the medical profession and of statisticians to bring about that result.

THE REGISTRATION OF MIDWIVES.

IN a recent issue of this JOURNAL allusion was casually made to the enumeration of midwives in the German Empire. A more careful examination of the document referred to shows that the number of midwives in the German Empire in 1898 was 37,025, an increase of 2.7 per cent. over the number which was found in a previous decade, the population having increased meanwhile 14 per cent., so that the actual ratio to the entire population had diminished.

A better mode of comparison is the ratio to the number of child-bearing women, which had diminished from 1 midwife to every 298 women of this age (seventeen to fifty years) in 1887 to 1 in 322 in 1898.

The distribution of midwives in the German Empire differs essentially from that of physicians, since the latter are more numerous in the cities, when compared with the general population, while the midwives are more numerous in the country districts. In the great cities there are 45 midwives to every 10,000 inhabitants, but in the smaller districts there are 85 to every 10,000.

When compared with the births, living and stillborn, it appears that there was a great difference in the various districts, from a maximum of 1 midwife to every 18 births in Waldeck in 1897 to a minimum of 1 to every 121 births in Hamburg, the average for the German Empire being 1 to every 54 births.

Information upon this subject relating to the United States is very meagre and unsatisfactory. The only general information is that of the United States census, in which, unfortunately, nurses and midwives are classified together. The whole number of the combined class found at the census of 1890 was 47,586, of which 3,745 were in Massachusetts.

The figures of the State census upon this point are also of little value. For example, at the State census of 1865, 1,119 nurses and 5 midwives were found and enumerated. In 1875 there were 2,267 nurses. In 1885 there were 3,266 nurses, and 29 midwives, and in 1895 there were 4,472 nurses and 41 midwives. To any general practitioner of several years' practice, either in city or in country these figures are simply incredible, and undoubtedly show that a large number of midwives must have either escaped enumeration altogether, or must have been classified as nurses.

The mortality from puerperal fever and the incidents of childbirth have been materially diminished since the introduction of antiseptic methods in the lying-in chamber, but the deaths from these causes in Massachusetts alone still number several hundred in each year, and there is a growing belief in the profession to the effect that a considerable part of this mortality is due to the want of proper training among this class of attendants, and is therefore clearly preventable. There appears to be good and sufficient reason for requiring the application of at least a simple form of registration to those who pursue this important branch of medical practice, if not the addition of a reasonable degree of qualification for the performance of their duties. Laws requiring such registration are already in force in several States, and may also be reasonably enacted in Massachusetts.

The following extract shows to some extent the laxity of English law in regard to midwives:

Recently, at an inquest held by Mr. Braxton Hicks, it transpired that a midwife in Lambeth had certified that a child seven days old had died from inanition and convulsions. No medical man had been called to attend the child, which had been ill several days. The coroner, having ordered a post-mortem examination in this case, a fracture of the skull was discovered, which had caused death from pressure on the brain. The midwife in question stated that she had attended 7,000 cases, and had given death certificates whenever she thought it right. The registrar had always accepted them. They had been so far accepted, in fact, for twenty years.[1]

Dr. Walford, who quotes the foregoing incident, also states that the registration of still births is not required in England, and that burials without registration are known to occur. The registrar general also cites a case of the opposite kind, where a certificate of death was accepted by a registrar, no death having taken place.

A NEW KIND OF DOCTOR.

THAT sheer persistence and sustained, if misguided, effort commend themselves to the average optician of today, let the following testify.

In the evolutionary process of the optician the assumption of the doctor's title, whether legally or not, represents to him the highest form of development. Prior to the formation of the Medical Board of Registration such doctors filled the land, and it was no unusual thing to hear a well-to-do person announce that Dr. Opticus treated his eyes, the trouble meanwhile being unrelieved.

With the advent of the Board of Registration, however, and its increasing activity, these mushroom medical men disappeared as quickly as they had grown. True, one or two hardier spirits still exposed signs

[1] From a paper by Dr. E. Walford, Medical Officer of Health of Cardiff: Public Health, London, January, 1901, page 265.

which apprised the passer-by that the "doctor" still treated eyes, but after it was apparent in several instances that the board would tolerate no misuse by the laity of the term doctor, and backed up its position in the matter by prosecution and fines, even these disappeared.

Then there was a distinct transition period and lo! the "eye specialist" had arrived. On signs in letters, in many instances, a foot long, one who ran might read that John Smith, "Eye Specialist," would examine and treat the eyes. But even this was considered too much by the finicky gentlemen of the board, and peremptory notices that all such advertisements must cease produced an immediate effect in all but one case. The individual was duly prosecuted, sentenced to an imprisonment of three months, and a fine of five hundred dollars, in the Municipal Court. This sentence was sustained in both the Superior and Supreme Courts, the last ruling that if the defendant held himself out as an eye specialist he held himself out as "one who devoted himself to a branch of the healing art which is the profession of the physician and surgeon," and that "if the defendant held himself out as an eye specialist he held himself out as a physician and surgeon within the meaning of the statute." Again there was rapid changing of signs.

But the title so dear to the heart of the optician must be obtained in some way, otherwise how is he to be addressed as doctor across the counter? So now we have the third phase, which at least has the saving merit of being original. The New England Optical Institute has started with a free clinic on one of the streets of Boston. Any one who applies for treatment receives a card which states that he is the patient of a physician, who has for assistants thirteen opticians with names duly printed on the card, and this institute, which offers a course of instruction, has petitioned the General Court for the authority to grant two degrees — Bachelor of Optics, and Doctor of Physiological Optics. They are to be doctors at last, if the bill as brought in becomes a law. Can it be that the day is coming when the ambitious maker of obstetric forceps, who has read up some of the physical laws underlying traction, will hold himself out as an obstetric specialist, and wish special legislation and a degree?

MEDICAL NOTES.

EXTERMINATION OF MOSQUITOES IN HAVANA. — On the ground that recently made experiments prove beyond reasonable doubt that mosquitoes convey yellow fever, a systematic attempt is being made to exterminate the breeding places. Forty sanitary inspectors of the city have been ordered to make a thorough inspection of their districts and to report all stagnant water where mosquitoes might breed. Twice a month petroleum, which cannot be drained off, will be thrown upon the stagnant water, in order to kill the embryo mosquitoes. The department will also attempt to kill all mosquitoes in houses where cases of yellow fever appear.

LEPROSY IN CRETE. — A medical inspection of the island of Crete reveals the fact, according to the *Journal of Tropical Medicine*, that there are 380 known lepers in the island, but the actual number is believed to be double that figure. A leper asylum is contemplated for their reception. It is interesting to note that although lepers have been allowed to roam about at their will, their numbers are stated to be rapidly decreasing.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, January 23, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 139, scarlatina 40, measles 63, typhoid fever 18.

AN APPROPRIATION FOR LABORATORY INVESTIGATION. — According to the December *Monthly Bulletin* of the Connecticut State Board of Health, "During the present session of the legislature the State Board will ask for a moderate appropriation to enable it to offer gratuitous examinations of morbid specimens from suspected cases of infectious diseases. In 1898 Vermont established a hygienic laboratory, appropriating $7,500 a year for running expenses. After two years of experience with it, so highly was its work appreciated that the annual appropriation was increased to $10,000. Several other States are enjoying similar advantages, and still others are asking for them."

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A meeting of the Society for Medical Improvement, held January 1st at the Boston Medical Library, was devoted to the history of the organization, which dates from 1828 and its incorporation from 1839. Dr. J. G. Mumford read a paper on "The Story of the Boston Society for Medical Improvement," which was followed by felicitous speeches from Drs. J. C. White, Morrill Wyman, C. J. Blake, R. H. Fitz and G. B. Shattuck, for the most part reminiscent.

LOW DIPHTHERIA DEATH RATE IN CAMBRIDGE, MASS. — The number of cases of diphtheria reported last year in Cambridge was among the highest in the history of the city, but the proportionate number of deaths was the lowest in many years. There were 925 cases. Seventy-two of the patients died, that is, 7.83% of the total number. The Board of Health attributes the comparatively low death rate to the use of antitoxin.

SMALLPOX IN VERMONT. — Two cases of smallpox have recently been discovered in Shaftsbury, Vt. The usual precautions have been taken to prevent the spread of the disease, which probably was introduced from New York.

WALTHAM BACTERIOLOGICAL LABORATORY. — In the near future the bacteriological laboratory in Waltham will be transferred from the Waltham Hospital

to the residence of Dr. Chadwick, physician of the Board of Health. The assigned reason for the transfer is that the hospital is situated too far from the centre of the city.

NEW YORK.

ELECTRIC ROAD HELD RESPONSIBLE. — In a decision recently handed down the New York Court of Appeals recognizes the responsibility of an electric railroad company for compensatory damages to a person injured by being thrown down by the jerk of a car in starting. A woman passenger on the Brooklyn Heights Railroad who had been injured in this manner secured $4,000 damages in a suit against the company. On appeal this verdict was set aside, the court holding that there was contributory negligence on the part of the passenger; but the Court of Appeals has reaffirmed the original judgment given for the plaintiff by the trial court.

AN APPROPRIATION FOR IMPROVEMENT OF WATER SUPPLY. — At a meeting of the Board of Estimate and Apportionment held January 18th an appropriation of $4,025,000 was made for immediate work in improving the water supply of the city. The plan of the city officials at present is to appropriate each year from $5,000,000 to $10,000,000 for making additions to the water system, so that in the future there need be no fear of a water famine during a severe drought. This action is regarded as putting an end to any effort to make a contract with the Ramapo Company for a water supply to the city.

PETITION TO SUSTAIN THE PATHOLOGICAL INSTITUTE OF THE NEW YORK STATE HOSPITALS. — At the last meeting of the Medical Association of the Greater City of New York a resolution was adopted petitioning the governor to sustain the Pathological Institute of the New York State Hospitals for the Insane, and protesting against the threatened subversion of the work of the institute which has been so highly commended by the scientific men of this and other countries. Similar petitions are being sent by other medical societies and privately by prominent physicians.

A VERDICT FOR GAS POISONING. — Mrs. Fredericka von Mechow has secured a verdict of $9,000 in a suit for $25,000 damages, in the Supreme Court, against the New Amsterdam Gas Company, for the loss of her husband. She asserted that the company, in changing the meter in the house where she lived, left the connecting pipes in such a condition that there was an escape of gas during the night which poisoned all the family and caused the death of Mr. von Mechow. The case is said to have no precedent.

REINSTATEMENT OF DR. MOORE AT BELLEVUE. — Dr. J. W. Moore, the interne at Bellevue Hospital who was in charge of the alcoholic and insane wards at the time of the death of Louis C. Hilliard, and who was temporarily suspended from duty after that occurrence, has now been reinstated on the house staff by the commissioner of public charities. The case of Dr. Moore was submitted to the Medical Board of the hospital, who exonerated him from all blame in the matter.

STATISTICS OF BIRTHS AND DEATHS. — The Health Department's reports show that during the year 1900 the number of deaths recorded in the Borough of Brooklyn was 23,475, against 22,572 births. Dr. Byrne, the head of the Bureau of Records in that borough, states, however, that in reality the births considerably outnumber the deaths, for while every death is necessarily reported, many physicians, as well as midwives, fail to report births.

PUBLIC HEALTH. — Dr. Nelson H. Henry, member of the legislature from New York, has been appointed chairman of the Assembly Committee on Public Health. At a meeting held January 10th the State Board of Health protested against Governor Odell's proposed plan for a single-headed commission, and expressed the opinion that such a change would not be in the interest of economy, as suggested in the governor's message.

OFFICERS OF THE MEDICAL SOCIETY OF THE COUNTY OF KINGS. — At the annual meeting of the Medical Society of the County of Kings (Brooklyn), held January 16th, the following officers were elected: President, Dr. Wm. Browning; Vice President, Dr. Henry A. Fairbairn; Secretary, Dr. David Myerle; Treasurer, Dr. O. A. Gordon; Directing Librarian, Dr. J. M. Winfield; Trustee, Dr. George R. Fowler.

DEATH REVEALS HER SEX. — It was not until the time of her death that Murray H. Hall, who kept a well-known employment agency, and who had passed as a man for over thirty years, was found to be a woman. During this time she had been twice married to other women and had attained considerable notoriety as a Tammany Hall politician. The cause of death was cancer of the breast.

BEQUESTS TO HOSPITALS. — The will of James D. Sarven, who died last April, left his residuary estate to several charitable institutions. The settlement of the estate has just been completed, and it is announced that St. Luke's Hospital and the Presbyterian Hospital, of New York, will each receive $59,140, and the Tarrytown Hospital, $5,000.

PORTRAIT OF THE LATE DR. AUSTIN FLINT. — On January 17th a portrait of the late Dr. Austin Flint, by George R. Boynton, was presented to the New York Academy of Medicine. Dr. E. G. Janeway made the presentation speech in behalf of himself and fourteen other fellows of the academy, who were the donors of the portrait.

NECROLOGIST OF THE NEW YORK GENEALOGICAL AND BIOGRAPHICAL SOCIETY. — At a meeting of the Board of Trustees of the New York Genealogical and Biographical Society held January 16th Dr. Ellsworth Eliot was elected necrologist.

DEATHS FROM INFLUENZA. — During the three weeks ending January 12th the number of deaths reported in the city from influenza was respectively 11, 36, and 75. In the corresponding weeks of last year the number was respectively 4, 8, and 9.

Miscellany.

IMMUNITY.

IT is not unusual in the experience of bacteriologists at one time or another, when raising the virulency of a strain of bacteria by passing the virus through a series of rabbits, to find every now and then certain of them which are unaffected by the inoculation. This individual immunity is often noticeable in man, for in any serious outbreak of diphtheria, plague, smallpox, or typhoid fever, there will be found those who not only may be in attendance on infected cases, but may also be in far from good health themselves, and who yet do not contract the disease. The cut-and-dried explanation of the above generally given is that the reason they do not suffer from the epidemic is that they are naturally immune, leaving, however, the question of why it is so unanswered. It has been lately shown that the Arabs as a race are immune from enteric fever, and the theory has been advanced that the immunization is attained by reason of the fact that the Arab in childhood is habitually accustomed to drinking foul, unwholesome water. It has been further pointed out by those who support these views that army medical statistics show that diseases of the digestive canal are twice as frequent among European troops as among the native soldiers in Algeria and Tunis. In traumatic infections the serous membranes of the Arab are very resistant, and particularly the peritoneum and the pleura, which probably accounts for the very exceptionally favorable results in abdominal surgery among the Arabs.

In striking contrast, however, with the above, it is found that Arabs as a race are singularly subject to pulmonary affections, and exhibit a very marked susceptibility to pneumococcal infection. Exceptions in regard to infections are very interesting studies, but it would seem difficult to establish the fact that there is such a condition as absolute racial immunity. In the case of anthrax, though it is very fatal for ordinary sheep, Angora sheep are not affected by it, and in the same manner ordinary rats are susceptible to anthrax, whilst white rats are immune, but these statements do not apply if the animals are placed under abnormal conditions. — *Medical Press.*

Correspondence.

THE PHYSICIANS' HOME; EAST TENNESSEE MOUNTAINS DESIGNATED AS A LOCATION.

MINOR HILL, TENN., January 12, 1901.

MR. EDITOR: By the Physicians' Home we mean a home, or retreat, for the aged and prematurely debilitated physicians of the United States. There are those in our ranks whose infirmity forces them to rest about one-half of their time. They go to one climate and another paying fancy prices for their changes. This home, or retreat, is for those — a place where they can go, breathe the pure air, fish in the streams, climb the mountains, look for minerals, raise fruits, vegetables, vineyards, orchards, poultry, etc. Such a home, with a well-organized board of directors, would be of incalculable benefit to the American medical fraternity. It would be an honor to our Commonwealth.

But one says, "How is such a home to be maintained?" In the study of this problem we have realized the fact that necessarily we would have to have the secretaries of all State and county medical societies collectors, so that when the annual expense account was due the members and all physicians in the county could hand it in to their secretaries. In this way it would be a very easy matter to correctly carry on the business.

Now as to the fund and how raised: There are 117,523 physicians in the United States. Say that one-half of these make a donation or subscribe a few dollars, this will amply erect the building and buy all the land necessary. Say the same number pay annually a few cents to the county collector, this will defray the expenses of the home. What we want is about 100 acres of farming land to be utilized in orchards, vineyards, gardens, poultry-yards, dairying, etc., and a commodious building. This will require an expenditure of about $150,000. We desire to say to those who have not reflected over the matter, that this move has been going on about six months, during which time it has received many cheers; received the endorsement of some of the best medical men in our government; yet, however, we have not given it wide publicity solely because it takes, in such a large enterprise as this, much labor and co-operation to effect publicity. During the time I, having been advised to do so, appointed a Committee on Location consisting of Drs. E. F. Williams, De Pere, Wis.; J. M. Hole, Salem, O.; O. C. Anderson, Holston Bridge, Va.; Douglass Hayes, Tracy City, Tenn., and Chalmers A. Parker, Fort Worth, Tex. They, after careful search into the matter, taking into account the geographical division, climate, access, cost of living, etc., have given their opinions in favor of the mountains of East Tennessee, settling as the future spot upon which to erect this home at Bristol, Tenn.–Va., a twin city of about 12,000 inhabitants on the line of Tennessee and Virginia, midway between New York City and New Orleans. Of course this location is open for approval or disapproval. Any one interested in location of this medical home should investigate and give his opinion, then should Bristol not meet with approval a new committee should be appointed. As to the healthfulness of this region, Ex-Gov. Taylor, who was reared in the mountains of East Tennessee, can inform you.

The people of Bristol, Tenn.–Va., are exceedingly anxious to have the home materialize there and have offered a large bonus in the way of some property situated at Fairmount, on an elevation overlooking the mountains. This property is actually worth over $100,000, but the offer for consideration before the American medical fraternity is $35,000. A committee should be appointed when this fund is raised to examine this property. There should not be anything definitely done until the whole regular, ethical profession is consulted.

I visited Bristol, Tenn.–Va. (the main street is the State line), on December 21, 1900, meeting representatives of the Committee on Location and other physicians, at which time we effected a temporary organization, electing Dr. G. M. Peavler, Bristol, Tenn., president; Drs. C. A. Abernathy, Pulaski, Tenn.; Chalmers A. Parker, Fort Worth, Tex.; Francis M. Prince, Bessemer, Ala.; A. Garcelon, Lewiston, Me.; J. W. Smithwick, La Grange, N. C.; J. C. Anderson, Holston Bridge, Va., vice-presidents; Dr. N. H. Reeve, Bristol, Tenn., secretary; Dr. Jno. S. Harris, Minor Hill, Tenn., corresponding secretary; Dr. Jno. C. Anderson, president National Bank of Bristol, Bristol, Tenn., treasurer.

With a well organized board of directors, a board of council, we cannot see why this home cannot be a financial

success. It can be and should be the pride and glory of every American practitioner. It is the first attempt in the history of any nation.

True life draws nigher
Every year.
And the morning star climbs higher
Every year.
Life's hold on us grows slighter,
And the heavy burden lighter,
And the immortal dawn brighter,
Every year.

This home is to be consigned to the prosperity of this, the most glorious nation on earth. It is to be dedicated to the memory of our forefathers in medicine; to the regular ethical profession of medicine in the United States; to the American Medical Association; to the various State and county (State, State divisions and municipal) medical societies. Any practitioner of regular medicine can contribute to the fund and enjoy its benefits whether a graduate or not. If you are a member of a medical society give us your secretary, also other members. If not a member give us the names of the physicians in your town or county. Take an interest in this, the most important enterprise of the twentieth century. Let a fraternal brotherly love reign throughout America.

Very truly yours,
JNO. S. HARRIS, M.D.

RE "KIRKES' HANDBOOK OF PHYSIOLOGY" IN AMERICA.

LONDON, January 5, 1901.

MR. EDITOR: My attention has been drawn to the reviews of two books each bearing the title of "Kirkes' Handbook of Physiology," which appeared in your issue of the 8th of November last and to the subsequent correspondence arising therefrom.

As my name is stated to appear in conjunction with that of my late colleague, Mr. Morrant Baker, upon the title page of one of these editions, perhaps you will be good enough to allow me to supplement, in one or two particulars, the history of this well-known textbook subjoined by your well-informed reviewer, and at the same time to make clear what has been my connection with it.

In the year 1848, Dr. Wm. Senhouse Kirkes, assisted by Mr. (afterwards Sir James) Paget, who was at the time lecturer on general anatomy and physiology at St. Bartholomew's Hospital, brought out a "Handbook of Physiology," which was largely based upon Dr. Baly's translation of "Müller's Elements of Physiology," the first edition of which in English was published in 1837. Four editions altogether appeared of the handbook under the same auspices. The fifth edition, then called "Kirkes' Handbook," was brought out in 1867 and was edited by Mr. Morrant Baker, who continued to be sole editor until 1880, when I assisted him in editing the tenth edition. The book, still called by the same title, continued under our joint editorship until 1892, when the thirteenth edition was published. In 1894 a revise of this edition was issued which was done, as far as I can recollect, by myself. After this we resigned the joint editorship and since then have had nothing whatever to do with the book.

The fourteenth edition was edited by Professor Halliburton and he, having a freer hand, considerably altered the book, enlarging its scope, rearranging the subjects, and judiciously pruning the parts which required that operation. The result of his work was to produce almost a new handbook of physiology, which might well have received his name instead of the old title. Naturally the majority of the illustrations, many of which had been produced at great expense, were retained, as was also, to a large extent, the histology. In the subsequent editions Professor Halliburton has continued his efforts to keep the work well in the van of physiological progress and I think that in his hands the gloomy forebodings of your reviewer, "that in a few years this publication will be a thing of the past" will go unfulfilled.

Such being the case, how comes it that an edition of "Kirkes' Handbook" is still published in America having upon its title page the names of editors who gave up all connection with the work in 1894? I am afraid the phenomenon can only be explained by the mysterious workings of the publisher's conscience in America! This, however, I do know, that the continued use of the names of Mr. Morrant Baker (whose lamented death took place in 1896) and myself upon the title page of any edition of "Kirkes' Handbook" is entirely unauthorized and is, in my opinion, unjustifiable.

I remain, dear sir,
Yours very truly,
VINCENT DORMER HARRIS, M.D. (Lond), F.R.C.P.

ELECTRIC AUTOMOBILES A SOURCE OF ELECTRIC LIGHT.

JAMAICA PLAIN, January 17, 1901.

MR. EDITOR: It may be interesting to the medical profession to know of a new use to which the electric automobiles can be put, that will be valuable not only to physicians, but to their patients. For the past two months I have been using an electric automobile, to the exclusion of the horse. On the afternoon of January 10th, on visiting a patient, I found it would be necessary to operate upon her that evening. Realizing the seriousness of the case and the delicacy of the operation, for it would have to be a laparotomy, it troubled me a little to know how to provide sufficient light to enable us to explore the abdomen thoroughly and safely, as etherization by gas or lamp light is not without its dangers. About 5.30 P. M., while riding around in the automobile, the thought came to me suddenly that I might utilize the electricity in my carriage to provide light for the operation. I immediately arranged for a long insulated wire about 40 feet, to which was attached an incandescent light with a reflector, using a 52-volt 6-candle-power lamp, also a 100-volt 16-candle-power lamp. I also had several spare ones in case one of them should burn out during the operation.

The automobile was run up on the patient's lawn by the side of the house, under the window, and the wire attached to the battery. We then drew the other end into the second story window, and running a strong line across the room, suspended the lamp from it over the operating table. On turning on the power, we had a most brilliant light, and coming from a storage battery, it was steadier and more uniform than the ordinary incandescent light, lighting the whole room — a large one — and giving perfect light to the operator, so that the laparotomy was performed with ease and comfort. In fact, the light was as good as in any operating room in Boston, and proved very successful in every particular. We burned it for over two hours, and could have burned it all night if necessary. It was a very rainy night with snow on the ground, which had no effect on the light or battery.

It seems to me that the results of that evening will prove valuable to physicians, because now we may have perfect light in any house, whether in the country or in the city, with no trouble, and the most delicate operation may be performed as easily and safely in the night as it could be by daylight. An automobile may be taken anywhere for such purposes, and surely this makes the electric carriage of even more value to physicians. Other fields are thus opened up for their usefulness to us which I will not enlarge upon at this time, but will simply mention the possibilities of utilizing them for cauteries, giving electricity to patients, etc., by attaching the proper appliances to them, which can be done easily and readily.

Very truly yours,
JOSEPH C. STEDMAN, M.D.

METEOROLOGICAL RECORD

For the week ending January 12th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Deaths reported 2,576; under five years of age 679; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 538, acute lung diseases 572, consumption 278, diphtheria and croup 108, diarrheal diseases 39, typhoid fever 39, scarlet fever 18, whooping cough 15, measles 5, cerebrospinal meningitis 2.

From whooping cough New York and Baltimore 4 each, Pittsburg 3, Boston, Cambridge, Somerville and Everett 1 each. From cerebrospinal meningitis North Adams and Clinton 1 each. From scarlet fever New York 12, Pittsburg 3, Boston 2, Worcester 1. From measles Boston 3, New York 2. From typhoid fever New York 13, Pittsburg 12, Baltimore 5, Boston 4, Cambridge, Springfield, Somerville, Newton and Newburyport 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending December 29th, the death rate was 16.9. Deaths reported 3,773: acute diseases of the respiratory organs (London) 325, whooping cough 88, diphtheria 78, measles 59, fever 46, diarrhea 34, scarlet fever 29.

The death rates ranged from 9.5 in Huddersfield to 23.2 in Hull: Birmingham 18.2, Bolton 14.0, Bradford 15.2, Bristol 16.2, Cardiff 10.2, Derby 16.9, Gateshead 19.5, Halifax 10.9, Leeds 18.3, Liverpool 22.4, London 16.7, Manchester 19.4, Newcastle-on-Tyne 20.9, Nottingham 17.2, Plymouth 15.8, Portsmouth 13.6, Salford 20.1, Sheffield 19.2, Sunderland 15.2, Swansea 16.3, West Ham 13.9, Wolverhampton 12.2.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 19, 1901.

J. B. DENNIS, assistant surgeon, to delay reporting for duty at Naval Academy until January 21st.

J. C. PRYOR, assistant surgeon, ordered to duty at Naval Hospital, New York.

R. B. WILLIAMS, assistant surgeon, detached from the Navy Yard, New York, and ordered to the Pensacola Navy Yard.

T. M. LIPPITT, assistant surgeon, detached from the Naval Hospital, Yokohama, Japan, and ordered to the Naval Hospital, Mare Island, *via* "Solace."

B. L. WRIGHT, assistant surgeon, detached from the Naval Hospital, Yokohama, Japan, and ordered to Naval Hospital, Mare Island, per "Solace."

RESIGNATION.

FREDERICK S. WARD, M.D., who has for the past two years had charge of the pathological work of the Taunton, Mass., State Hospital has resigned.

BOOKS AND PAMPHLETS RECEIVED.

The Anthropometric Manual of Amherst College. 1900.

Aseptic Minor Gynecology with Demonstrations. By Augustin H. Goelet, M.D. Reprint. 1900.

Transactions of the American Gynecological Society for the Year 1900. Vol. XXV. Philadelphia. 1900.

Twenty-Second Annual Report of the State Board of Charity of Massachusetts, January, 1901. Boston. 1901.

The Failure of the Consensus Judgment with Reference to Tuberculosis. By Charles Denison, A.M., M.D., Denver, Col. Reprint. 1900.

Revised Interpretation of the Central Fissures of the Educated Suicide's Brain Exhibited to the Association in 1894. By Burt G. Wilder, M.D. Reprint. 1900.

Medico-Surgical Aspects of the Spanish-American War. By Lieut.-Col. Dr. Nicholas Senn, Chief Surgeon, U. S. Volunteers, etc. Chicago: American Medical Association Press. 1900.

Medical and Surgical Reports of the Boston City Hospital. Eleventh Series. Edited by Herbert L. Burrell, M.D., W. T. Councilman, M.D., and Charles F. Withington, M.D. 1900.

If an "Isthmus Rhombencephali" Why Not an "Isthmus Prosencephali?" A New Head-Rest for the Removal of the Human Brain. By Dr. B. B. Stroud, Cornell University. Reprints. 1899, 1900.

Nephrorrhaphy. Address in Obstetrics. Proctorrhaphy: The Suspension of the Rectum for the Cure of Intractable Prolapse and Inversion of that Organ. By Charles P. Noble, M.D., Philadelphia, Pa. Reprints. 1900.

A Clinical Study of the Lymphatic Glands in One Hundred Cases of Scarlet Fever. A Clinical and Pathological Study of the Rash of Scarlet Fever. By Jay F. Schamberg, A.B., M.D., Philadelphia. Reprints. 1899-1900.

A Guide to the Instruments and Appliances Required in Various Operations. By A. W. Mayo Robson, F.R.C.S., Senior Surgeon to the Leeds General Infirmary, etc. Second edition. London, Paris, New York, etc.: Cassell & Co. 1900.

A Textbook of Pharmacology and Therapeutics on the Action of Drugs in Health and Disease. By Arthur R. Cushny, M.A., M.D. (Aberd.). Second edition, revised and enlarged. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1901.

Physical Diagnosis in Obstetrics: A Guide in Ante-partum and Post-partum Examinations for the Use of Physicians and Undergraduates. By Edward A. Ayers, M.D., Professor of Obstetrics in New York Polyclinic, etc. Illustrated. New York: E. B. Treat & Co. 1901.

THE TREATMENT OF THE LATER PHASES OF HEART DISEASES.[1]

BY JOHN L. HEFFRON, M.D., SYRACUSE, N. Y.

My subject is as old as the art of medicine. The treatment of the later phases of chronic heart diseases has engaged the serious attention of medical men of all ages and of all nationalities. There is no expectation on your part that any new method of treatment is to be proposed in the course of this paper, or that any claim to fresh discoveries that can actually cure conditions long recognized as incurable will be attempted. Indeed, the subject may be considered by many as worse than "threshing of old straw," and many may feel that in the management of such conditions as must in the end inevitably lead to death, there is no inspiration, and that time spent in the discussion of the amelioration of distressing symptoms resulting from an incurable malady might better be given to more important matters. But is this true? How much of the life of every physician is of necessity given to those whom he knows he cannot cure? If we exclude the diseases which are self limited and lead naturally to recovery, and in the management of which the wise physician accurately observes the evolution of symptoms, and resolutely refuses to complicate the situation by active interference when such interference is not positively indicated, and those cases in which the imagination of the patient concocts diseased conditions out of the results of imperfect modes of life (and this is the large field in which the charlatan reaps his enormous harvest), and then excludes those conditions which the surgeon's skill alone can cure, we shall discover that at least one-fourth of our time is consumed in the treatment of chronic ailments ultimately and of a necessity fatal. Is, then, such a proportion of our time and energy wasted? Put yourself in the place of your patient.

If one could have his ability to work even partially restored, or in such an autumn as this, if one could but sit at a window with body at ease and watch the wonderful close of a summer's glory, or if, with greater vigor, one could go forth and enjoy the procession of the seasons and exult in nature's various moods, or, if even helpless, he could lie comparatively free from pain, and for a brief period longer look into the eyes of affection, would it not be well worth all the effort and all the sacrifice of time and energy on the part of the attending physician whose skill made the prolongation of such enjoyments possible? As long as human nature remains unchanged, so long will the desire for life, even under adverse conditions, be dominant.

To limit the discussion within reasonable bounds we will consider only cases of chronic endocarditis, and, to define what is intended by "the later phases of chronic heart disease" will indicate that it is meant to cover that period of time, short or long, after compensation has once failed.

Let us briefly review the conditions which may supervene upon failing compensation. So long as the circulation is maintained at its normal standard, the subjects of chronic heart disease are able to go about their ordinary avocations with usual ease and comfort, however much fuss the heart may make in accomplishing its task, and they are made aware of circulatory defect only upon some severer exercise than is their wont, or by some atrocious errors in diet. It is the commonest experience for a physician to detect a heart lesion in the course of a physical examination of a person in whom the heart is not under suspicion. Indeed many subjects of long-standing chronic endocarditis never come under professional observation until beginning failure of compensation forces upon their attention symptoms the nature of which they do not suspect. What then is the pathologic groundwork of our therapeutic problem? Chronic endocarditis results in the disabling of one or more valves of the heart in every instance. In many cases there is also the implication of other intracardiac structures, as an atheromatous deposit in the lining of the ventricles, changes in the papillary muscles, and alterations in the tendons guying the valves. There is always change in the musculature of the heart. Hypertrophy of the muscle upon which extra work is put is nature's law. When this hypertrophy is unequal to the demand upon it, a hollow muscular organ undergoes dilatation, and this process is frequently accompanied by a degeneration of the muscular substance, the most frequent type of which is the fatty infiltration. When the heart becomes unequal to its task a circulatory crisis occurs marked by venous engorgement of all tissues and organs. This is manifested by impaired digestion, imperfect elimination of waste products, loss of strength, restlessness, disturbed sleep, and rapidly rising dropsical effusions into the cellular tissues and later into the serous cavities. Sclerotic changes in arterial walls ultimately result and not infrequently interstitial nephritis supervenes. If this hasty sketch is in accordance with the facts, it follows that the treatment will be guided by (1) the condition of the heart; (2) the abnormal conditions resulting from a disturbed circulation, and (3) the general condition of the patient. These conditions are so mutually dependent one upon the other that it will be difficult to discuss each categorically. We are thus forced to proceed as we do with the patient before us, from general considerations to particular indications.

When compensation has failed, the first indication is to relieve the heart of all extra work. Rest in the recumbent position accomplishes this most perfectly as far as the postural treatment is concerned. It relieves the heart physiologically of from ten to twenty contractions per minute as compared with the usual conditions which prevail when one is simply "confined to his room" in the usual acceptation of that term. When dyspnea is marked this position is difficult of attainment at first, but can soon be accomplished under favorable conditions. The rest should be complete, and should include forbidding to sit up even during feeding and the necessary care of the excretions. Of nearly as great importance is the exclusion of visitors whose presence excites emotion of any kind.

Secondly, the volume of blood to be propelled by the heart should be diminished as much as possible. To accomplish this the direct diminution of the volume of the blood by blood letting is seldom indicated, though in extreme cyanosis not the expression of simple venous congestion most brilliant results have been

[1] Read before the Syracuse Academy of Medicine, December 18, 1900.

reported from blood letting and even paracentesis cordis. The use of such hydragogue cathartics as least disturb the general condition and most aid in the elimination of waste matters with the watery evacuations is imperative. For this purpose there are many candidates for favor, but my experience leads me to place the reliable remedies capable of accomplishing this purpose in the following order: elaterium, calomel, salines. At the same time the diminution of ingested fluids must be insisted upon. It is desirable for the nurse to keep a record of the relation of ingested fluids and excreta with as much accuracy as conditions permit. With the aid of such a record one can easily avoid errors on either side.

Thirdly, the distressing nervousness of the patient, which increases the irritability of a heart already overburdened, must be controlled. For this purpose ice bags over the heart give a certain amount of relief, but it is almost always necessary to employ remedies directly acting upon nerve centres. It is here that the alkaloids of opium can be administered without hesitation. Codeine should first be tried in doses of one-half grain hypodermically. It will usually suffice, and when it can be used it relieves the patient of the narcotic effects of morphine. It does not, however, differ from morphine in its effects upon the secretions and will as surely produce constipation as will morphine. If it fail to induce the desirable quieting effect and compel sleep morphine must be used. Both alkaloids stimulate rather than depress the myocardium if used in therapeutic doses. Heroin is a modern fraud. It is not a new alkaloid of opium, but a salt of morphine, and is in no way superior to the more familiar salts and lacks none of their evil effects. Already several cases of chronic morphine poisoning have come under my observation from the use of heroin and one of them was in a physician. If the nervousness is not so extreme though positive, I have obtained most gratifying results from the use of the abstract of cannabis Indica made by the late and ever lamented Dr. William Manlius Smith. The effect of this drug is frequently most happy, and it is free from the objectionable action on the various secretory organs. This preparation is so uniform and so efficacious that as a rule I use it at first, and if it fail add to it a small quantity of codeine or of morphine.

Closely related to this relief of all unnecessary work of the heart is the management of the diet. It is well known that a full meal causes increased action of the heart, first physiologically, then mechanically by the irritation of a distended stomach crowding against a crippled heart. If digestion is feeble and fermentation of food in the stomach take place, the crowding against the heart of a stomach distended with gas and imperfectly digested food may so disturb the heart's innervation as to produce even fatal results. The invariable rule must therefore be for such a patient to take small amounts of easily digested food, at such intervals as allow of the perfect elaboration of the ingesta. In the diet of these patients there are certain necessary exclusions. Substances which are bulky and of small nutritive value, and which are usually of slow digestion, as are most of the vegetables, foods highly seasoned with condiments which naturally stimulate the heart, preparations which represent chiefly the waste matter of other animals, like beef tea and all soups which chemically have an analysis closely resembling that of urine, all alcoholic beverages, and all acid fruits and vegetables, because so many chronic heart cases have a rheumatic background which demands alkalies, must be rigidly excluded. All these, without exception, impose an extra burden upon an already overburdened organ, and are non-essentials to nutrition, however grateful they may be to an overcultivated palate. The selection of the ideal dietary in each individual case must be the resultant of an intimate acquaintance with the patient's digestive ability and tastes, and a thorough knowledge of the nutritive value of food stuffs. In the diet of these patients during the past six months I have been greatly helped by a pure albuminous food representing the casein of milk, originally manufactured in Germany as a competitor of meat from an economic standpoint, known as Plasmon. It has little flavor or odor, and can be combined with many foods, but when Professor Virchow tells you he has in his own case obtained excellent nutritional results by using Plasmon for dinner to fortify a puree of potatoes and apples, you know his nationality at once, and will not be tempted to force that particular dish upon any but a German palate. Fresh eggs, raw or slightly cooked, custards, junket, scraped or chopped lean beef, mutton or chicken, the expressed juice of broiled beef or mutton, stale bread toasted, possibly a baked potato, with light milk puddings, make up a suitable dietary for average cases, while in those whose digestive ability is greatly impaired the various predigested foods, including peptonized milk gruels, the peptonoids, Just's food, etc., will serve to bridge over the interval during which the general condition is undergoing improvement, and the heart is recuperating its energies. The method of administering predigested foods is of considerable importance. Rather than give a comparatively large quantity at stated intervals it is productive of far better results to give small portions at very frequent intervals, letting the patient sip it by mouthfuls every fifteen minutes. Attention to so slight a detail as this will frequently give you control of a stomach rebellious from venous engorgement, and result in more perfect nourishment of your patient than is possible from any other means I have ever employed.

With these simple means, rest, diet and free catharsis, it is surprising how many cases are relieved from threatening symptoms, and are prepared for a more vigorous treatment which shall restore lost compensation.

Not infrequently, however, our services are first required in cases where failure of compensation has resulted in dropsy. Cardiac dropsy is first manifested by effusion into the cellular tissues farthest from the heart. Beginning in the ankles it gradually ascends to the trunk, then is added ascites, and later hydrothorax. Latest appears edema of the upper extremities, though in some cases this is observed previous to the appearance of hydrothorax. Though dropsy is but a symptom pathologically, it is a therapeutic entity. The indications for treatment are clear. The effused fluid must be reabsorbed from the tissues or cavities and be removed from the body. If this can be accomplished physiologically the effect is much more permanent than when the fluid is simply removed mechanically. Often, however, when all the cellular tissues and serous cavities are distended with serum, it is difficult if not impossible to get a physiological action of drugs until a certain amount of re-

lief is attained by mechanical means. It has been frequently observed that digitalis and all diuretics will fail to act until the dropsy has been somewhat relieved by other means and that after such relief the usual physiological action of a drug, say digitalis, will be manifested and complete the elimination. All three of the emunctories should be acted upon, the skin, the bowels and the kidneys, and usually means can be adopted whereby all three can be simultaneously influenced. If a patient is sufficiently strong the hot-air cabinet bath can be used daily, while on the same day the purgative effect of elaterium is obtained and the kidneys are stimulated to free action by the use of digitalis, squill or the acetate of potassium. The effect of the cabinet bath in my practice has never resulted in anything but good. Elaterium has almost never produced any unpleasant effects, and some diuretic has usually been possible of administration without disturbing digestion. If digitalis disagrees in the ordinary form of the tincture or the infusion, digitalin from a reliable maker can always be used and depended on for effect. If the nature of the heart lesion be such that digitalis is contraindicated, efficient doses of pure caffeine, which is much better than diuretin, will produce good results, or the acetate or bitartrate of potassium in an infusion of juniper berries can be given. In Trousseau's "Clinical Medicine" you will find a prescription for a diuretic wine which is today used in the Hôtel Dieu in Paris, and which presents in a form not unpalatable the combined virtues of squill, juniper, digitalis and the acetate of potassium. It can be made by any pharmacist and has often given me most gratifying results. If combined diuresis, diaphoresis and catharsis fail to give results in a few days, it is advisable to resort to mechanical aid in relieving the distended tissues. Before a resort to tapping is made it is my practice to puncture the skin of the dorsum of the foot and of the leg in many places. This must be done with all the aseptic precautions used in surgery. A sterile skin is rapidly punctured in many places by a sterile needle, and wrapped at once in sterile gauze by a nurse with sterile hands. Under such conditions I have never seen inflammatory reaction, and very recently I have seen a general anasarca so greatly relieved by such practice that Trousseau's diuretic wine with elaterium have completed the elimination of all the effusion in all tissues and cavities, so that the woman has gone down town on the street cars and completed her Christmas purchases without distress or great fatigue, though I am free to confess it was without my sanction or knowlege. If these means fail and the peritoneal cavity and the pleural sacs in addition to the cellular tissues are not relieved, it is imperative to resort to paracentesis. In my own practice, almost without exception, paracentesis for cardiac effusion has given only temporary relief. In other words, when the heart lesion is so great, or the muscular power of the heart so little, that with the means discussed no remedial effect is produced, the cavities emptied of fluid by paracentesis will refill more or less rapidly and require repeated operations for temporary relief until the patient's strength is exhausted and death supervenes.

The general condition of the patient under the treatment thus far indicated will almost uniformly improve. The stomach will ordinarily resume its functions, sleep will be possible and an increase of strength will develop *pari passu*. There is no reason, however, why the subjects of chronic heart disease should be deprived of the advantage of special treatment in case of impaired digestion or of insomnia or of any other intercurrent malady. To aid the complete retrograde metamorphosis of waste matter I have found the systematic administration of oxygen of very great value. If oxygen be deeply inhaled and retained as long as possible before expiration it enters the blood more freely and aids in the oxidation process much more than if simply administered with the inspired air in a haphazard way. Such a use of oxygen for fifteen consecutive inspirations is much more efficient than its repeated administration as ordinarily used. The stimulation of the liver by calomel with soda administered twice a week is of very great value in many cases and particularly in patients who have a tendency to the accumulation in the blood of imperfectly elaborated waste matter or who are the subjects of catarrhal processes in gastric or intestinal mucous membranes.

It remains now to review briefly the means at our disposal other than those already considered for improving the condition of the heart. It goes without saying that a valve once deformed cannot be restored to its normal state. There is a considerable list of cardiac stimulants all of which are of more or less value. It has always seemed to me that a knowledge of how to use effectively the best remedy is of greater value than a wide acquaintance with a long list of remedies of more or less doubtful value. So while I do not minimize the value of sparteine, cactus, convallaria, strophanthus and adonis vernalis, I do find that a careful observation of my results gives me ever increasing confidence in the intelligent use of that prince of all cardiac stimulants, digitalis.

Digitalis strengthens the systole and prolongs the diastole of the heart and increases arterial tension by its action on the vasoconstrictors. It is only this effect on arterioles that is sometimes not desired in chronic heart disease, and this chiefly when atheromatous changes have taken place, or wherever chronic interstitial nephritis has developed. A very common pathological sequence is rheumatism, endocarditis and interstitial nephritis. In such cases and in the aged if the temporary stimulation of the heart is imperative, the effect of digitalis on the arterioles can be overcome by the use of nitroglycerin without interfering with the action on the heart. Digitalis is best administered in the form of the fresh tincture, or of the powdered leaves. According to the Pharmacopeia of 1890 eight minims of the tincture is equivalent to one grain of the leaves. The dose must be such an amount as is necessary to produce the desired effect. Seldom will it be necessary to exceed ten grains of the leaves in twenty-four hours, but there are cases in which success can only be obtained by the administration of a few very large doses of this drug. There are cases of cardiac embarrassment which are not due to ineffectual contractions of this hollow viscus, but to excessive action of an hypertrophied organ. Of course in such cases digitalis could but add to the embarassment, while aconite properly given will quickly equalize the circulation. It might be said right here that the routine administration of digitalis or of any other cardiac stimulant so soon as a cardiac murmur is diagnosed is most pernicious practice. Such drugs are only indicated

in failure of circulatory power, and the amount of fuss made by a heart in accomplishing its task is not the factor which indicates the necessity of any cardiac stimulant. In cases of sudden failure of cardiac power a quicker acting drug than digitalis is needed. Here nitroglycerin, alcohol, ammonia and strychnine are available and will support the heart until the tardier effects of digitalis can be obtained. Strychnine in large doses hypodermatically until improvement is manifest has often saved a life in imminent danger. The dose of digitalis is to be lessened as the heart increases in tone under the influence of rest and increased nutrition until it can finally be omitted; for, like all drugs, a tolerance is finally established and the desired effects in emergencies become impossible in those who have contradicted the digitalis habit. Digitalis is not a drug to be administered continuously and habitually, though its use may be necessary for a considerable length of time.

There are many other methods by which the musculature of the heart can be permanently strengthened. The heart is a muscle. It obeys the laws of muscles. If little is required of it, it works quietly and easily, if more, it increases in bulk and power. The re-establishment of lost compensative power must be the ultimate object of all therapeusis. Exercise increases the tone of muscles. So judicious and graduated exercises will increase cardiac tone. After the critical moments of a failure of compensation are passed successfully by the use of such methods as have been described, the training of the heart must begin. At first gentle massage, then passive exercises, later resistance exercises, and last voluntary exercises, such as driving, then walking, and even bicycling on level streets when patients are already masters of the mysteries of the wheel. The hill climbing recommended by Oertel is of greatest value in training feeble hearts if carefully carried out. Up the hilly streets of our city heart patients of mine and doubtless of other members of this academy daily walk. They mark their daily progress by the houses. They never overstrain the heart by going too far, for they are taught that excess is failure, and that beginning embarassment of respiration is a sign that return is imperative, and they are indoctrinated with the knowledge that when they go forth they must of necessity return, and return unexhausted, if therapeutic effect of their exercise is expected.

The treatment of the brothers Schott at Bad Nauheim was based upon scientific data. The effect of carbonated baths is stimulating to the nerve centres of the skin and to the general circulation. Combined with the use of graduated exercises, careful diet, and hygienic living it has accomplished much in the cases of those who have been able to carry out this "cure." It can be easily and successfully practised at home, and the baths natural to Nauheim imitated by art in any home possessed of bathing facilities.

The subject of chronic endocarditis must be taken into the entire confidence of his physician. He himself and not some member of his family must be told of his actual condition, for he can do for himself, if he can be brought to an intelligent conception of his condition, what no attendant can do for him. In matters of rest and diet and treatment, if he be resolute in his desires and intentions to recover, he can compel fate itself. If he, on the other hand, through ignorance or self will, cries out against this restriction or that necessity, he will quickly pay the penalty for transgression, and often by sacrificing life itself.

If, fortunately, a failing compensation be restored, as it can be in very many cases, the patient must be kept under frequent observation, and, though he may attend to his ordinary business, he must understand that excessive demands upon his powers, both physical and mental, are interdicted, and that the very condition of the prolongation of his life is moderation. Life under such limitations is often sweet and desirable.

PERITONSILLAR ABSCESS.[1]

BY F. C. COBB, M.D., BOSTON.

PERITONSILLAR abscess is a subject with which we are all more or less familiar. It is a disease usually limited to about a week's duration, very painful to the patient and more or less trying to the physician who punctures it, often with the result of only increasing the sufferings of his patient.

The object of this paper is to urge the use of a little more care and study in the relief of this disease.

The cause of peritonsillar abscess has been much discussed, some authorities asserting that it is due to suppuration in the loose connective tissue around the tonsil which starts *de novo* as does any boil elsewhere. Others believe that it is a symptom of the rheumatic diathesis, while still others think, as does the author, that it results from infection by the germs of acute tonsillitis. Whichever of these views be correct, the observation that it almost always is met with in conjunction with some tonsillar obstruction to the supratonsillar fossa will, I am sure, be granted by most specialists. The anatomy of the parts with reference to the pathology of peritonsillar abscess, has not been very carefully studied, but the consensus of opinion appears to be that it arises in the cellular tissue above, behind or in front of the tonsil. Chiari, however, believes that the abscess is formed in the pharyngomaxillary space, which is bounded by the tonsil, the internal pterygoid muscle, and the palatine arches (McBride). Injection of this space on the cadaver, as was done two years ago by the writer, certainly gives one the appearance of the ordinary peritonsillar abscess. This space also contains the great vessels, but is separated into two portions, an anterior and a posterior, by the stylopharyngeus muscle and its fascia. In the former Chiari believes that the pus forms, and being unable to force its way backward on account of the resistance offered by the stylopharyngeus, pushes forward and inward until it makes its exit through the pillars usually in front of or behind the tonsil.

This theory certainly seems to have some points in its favor, among which may be cited the difficulty or impossibility of obtaining pus without a very deep puncture in many cases, and the curious fact that peritonsillar abscess even when opened successfully through the anterior pillar will very often close, to open elsewhere later. If we assume the pharyngomaxillary space to be the seat of abscess, we have the constrictor of the pharynx with almost horizontal fibres and the anterior pillar, or palatoglossus, with nearly vertical fibres crossing it and forming a barrier through which pus must pass in order to make its exit through the

[1] Read before the Clinical Section of the Suffolk District Medical Society, December 19, 1900.

anterior pillar. If we puncture through these two muscles, whose fibres cross one another, as we should do in lancing a peritonsillar through the anterior pillar, our wound, in order to remain patent, must have its openings in the same relation to one another as they were at the time of making the incision. With a patient gagging and straining this relation is apt to be lost and the incision no longer remains open. That many punctures made through the anterior pillar do close, the period of relief being postponed some hours or days, I believe all would agree, although some cases have been seen to discharge continuously through the opening thus made. It has seemed to me that where pus had forced its way nearly to the surface of the anterior pillar so as to have agglutinated the various layers, we may expect success from puncture in this locality. Whether suppuration occurs in the pharyngomaxillary fossa or in the tissue around the tonsil is still an open question. Examination of pus from peritonsillar abscess yields the bacteria common to pus in other localities, namely, various forms of streptococci and sometimes a few pneumococci.

Diagnosis. — The diagnosis of peritonsillar abscess is usually easy after the first forty-eight hours. the familiar swelling of the soft palate and its one-sided appearance making a picture which it is not easy to mistake. The pain, short duration and violent inflammatory appearances are very characteristic. The cases which most require care in diagnosis are those in which the swelling has lasted some weeks and which are neither very much inflamed nor very painful. The diagnosis between sarcoma of the peritonsillar tissue, syphilis and subacute peritonsillar abscess is sometimes difficult, and a careful history is here of great value, especially as to length of time, previous attacks, pain or signs of lesions or metastases elsewhere. Peritonsillar inflammation is not accompanied by ulceration in any portion of the mouth or tonsil, while gummata or sarcoma are apt to be so associated. Usually in chronic peritonsillar swelling some discharge of pus may be found on careful examination, while puncture, if other means fail, will give us a clue to the diagnosis.

Symptoms. — The first symptom is usually a severe chill, followed by fever and headache and by pain referred to one side of the throat only. The pain is of a dull, throbbing character at first, but as the swelling increases it becomes sharper and more excruciating. Pain in the ear is a prominent feature, due probably to traction or pressure on the Eustachian orifice by the swollen tissues. Interference with respiration in adults is not usually so marked as in children, but deglutition is so painful that the patient often cannot even swallow his saliva, but allows it to run from his mouth rather than make the effort. In bilateral peritonsillar abscess the ordinary appearance is of course changed, as well as the symptoms of pain and throbbing on one side. The palate being evenly swollen presents no contrast; the uvula hangs in the middle line instead of being pushed away from the affected side. But the tonsils when carefully examined show no enlargement beyond the pillars, which ought to throw them into apposition with each other, and the pillars themselves are nearer the median line of the pharynx than usual. In my experience the bilateral condition is a rare one, and even where both sides are affected, one side tends to follow the other rather than to become inflamed at the same time.

Prognosis. — Cases of untreated peritonsillar abscess usually subside through rupture, which commonly occurs between the the pillars of the fauces. Their duration is about seven days, although I have records of cases where four days was the average length of time and others where two weeks was the usual one. It may be remarked here that the history of the duration of previous attacks is important in ascertaining the effect of treatment, for if we cannot succeed in aborting an attack in less time than nature usually does it, we gain nothing by operation. Usually the disease is self limited, but several cases are on record where the pus made its way into the posterior portion of the pharyngomaxillary fossa, and so into the mediastinum with a fatal result. Thrombosis of the large veins and pyemia have also resulted.

Treatment. — To abort an attack after peritonsillar swelling has appeared is, in my experience, impossible. When the patient feels an attack coming on, resort may be had to quinine, opium and diaphoresis on the same principle as we adopt to check a cold. Bosworth believes in the salicylates and other antirheumatic remedies, and gives large doses of 13 to 15 grains an hour of the salicylate of soda with a drop of Fleming's tincture of aconite until the physiological effects of numbness and tingling of the finger tips caused by the latter drug begin to appear, when its use is permanently discontinued. Of course drugs like aconite and the salicylates must be administered with great care and under very watchful supervision. Knox, cited by the same author, found this procedure efficacious in 40 out of 50 cases. I have tried the salicylates with much less good fortune, and believe that where swelling of the peritonsillar tissue exists only the knife can give any relief, while the salicylates on account of their depressing influence contribute to the exhaustion which follows this very debilitating disease. When we find the swelling increasing our efforts should be directed to bringing the abscess to a head as speedily as possible. For this purpose hot-water gargles repeated every half hour are as satisfactory as anything which we have used. But it is after the swelling is well under way, or three or four days following the onset of the disease, that we may do our best work in checking the abscess. At this point the general surgeon often lances the anterior pillar without obtaining pus, and even when he is fortunate enough to find it, the wound closes at once and the symptoms within a few hours recur with the same severity as before. In general, one may say that a deep puncture through the anterior pillar seldom remains open, while a shallow one not infrequently does so.

While the swelling is moderate the physician should study the condition of the anterior and posterior pillars of the tonsil with great care. The posterior pillar being behind, the inflamed mass of tonsil and anterior pillar often escapes observation. If swelling of the posterior pillar behind the crypts of the tonsil is present, we should examine it with a probe to assure ourselves whether it fluctuates or is simply swollen and edematous. If fluctuation can be obtained, a puncture, which with the application of cocaine is practically painless, should be made, and a cure results with very little discomfort to the patient. If the posterior pillar be normal in appearance, a careful examination of the anterior will often show a slight bulging at its junction with the tonsils and a very little dissec-

tion under cocaine in order to separate tonsil and pillar will give pus, which with a good-sized opening will discharge continuously. Should there be no signs of pus in either pillar the supratonsillar fossa must be sought as the most probable seat of the suppuration.

Here care must be used in the use of the knife, since the great vessels lie in the pharyngomaxillary space, and instances of death resulting from injuring them in this way are on record. The great vessels lie, however, in a plane posterior to one drawn through the posterior pillars, so that if we avoid penetrating the posterior pillar in the interior of the abscess we are safe from this danger. The arterial supply of the tonsil is derived from the dorsalis linguæ, the ascending palatine, the tonsillar, the ascending pharyngeal and the descending palatine arteries. Of these the only one of importance is the tonsillar, which is a branch of the facial. All these arteries enter the tonsil from its base, and we may avoid them by passing between the tonsil and pillar. If, therefore, we fail to find pus in either anterior or posterior pillar, we should enter the supratonsillar fossa, taking care not to penetrate further backwards than the posterior pillar. Should pus be obtained a wider opening through the tonsil may be secured. Cocaine should be used, either submucously or by application to the mucous membrane, in order to make the procedure as painless as possible.

RETROPHARYNGEAL ABSCESS IN THE ADULT.[1]

BY J. L. GOODALE, M.D., BOSTON.

THE case of retropharyngeal abscess which I have to report is of especial interest for two reasons, (1) because of the age of the patient, and (2) because of the demonstration of tubercle bacilli in the pus.

I shall not go into a general account of retropharyngeal abscess, but will simply enumerate certain salient points, before describing my own case: (1) It is quite an exceptional disease after the age of four. In regard to classification, Bokay distinguishes (1) idiopathic abscesses; (2) secondary abscesses from disease of the cervical vertebræ or from the irrigation of pus from a superficial cervical adenitis; (3) septic abscesses; (4) abscesses from trauma. Bokay suggests giving up the old term "idiopathic" and calling the abscesses coming under this head "retropharyngeal abscesses" from retropharyngeal lymphadenitis; thus separating them from the secondary abscesses, metastatic and traumatic, and permitting at the same time definite etiological knowledge. Bacterial invasion of the lymph glands behind the posterior pharyngeal wall will produce pathological changes in these structures similar to those occurring in other lymphoid tissues, giving rise, however, in view of their localization, to characteristic clinical symptoms.

Bacteriological examinations of the pus were made in a large number of cases of acute abscesses by Koplik, of New York, who found in every case streptococci. So far as my search in the literature goes, no case has been reported of tubercular retropharyngeal lymphadenitis in the absence of caries of the spine. Shurley, in his recent book, says that the statement of some observers that acute retropharyngeal abscess in some cases is tuberculous is unsupported by investigations.

The following case came under my observation June 14, 1900, in the throat clinic at the Massachusetts General Hospital in the service of Dr. Clark. The patient was a waiter, eighteen years old. He gave the history of the development four weeks ago, while in his usual good health, of swelling in the back of his throat, which had slowly increased in size up to the present time, unaccompanied by fever or other disturbances than those due to difficulty in swallowing. The patient was fairly well nourished, moderately pale, but not cachectic. Examination of the throat showed a bulging forward of the whole posterior pharyngeal wall, due to the fluctuant swelling extending downward from the level of the soft palate. The lower limit was not visible and no attempt was made to determine it by palpation. The mucous membrane covering the swelling was essentially normal in appearance. There was no evidence of disease of the cervical vertebræ. A free incision was made with a bistoury into the swelling and about four ounces of pus evacuated. The knife immediately after withdrawal from the abscess was carried to Dr. Wright in the pathological laboratory. Two syringefuls of a bouillon suspension of the pus were injected into a guinea pig. On August 4th, then seven weeks after the inoculation, the guinea pig was killed and showed all the characteristic lesions of tuberculosis. With regard to the subsequent condition of the patient, immediate relief followed the evacuation of the abscess. I have recently written, requesting him to come for examination. Although he has not reported in person, he wrote me November 14th that his throat had been in good condition since the operation and he was otherwise in good general health.

This seems unquestionably a case of tubercular retropharyngeal lymphadenitis, ending in suppuration. No point of entrance for the infection was found.

Medical Progress.

PROGRESS IN ORTHOPEDIC SURGERY.

BY E. H. BRADFORD, M.D., AND F. J. COTTON, M.D., BOSTON.

CONGENITAL DISLOCATION OF THE HIP.

LORENZ, in a valuable book published in 1900, in the treatment of congenital hip dislocation, considers it as proved that the chief obstacle to reduction lies in the soft parts. The obstruction offered by the shortened muscles, fasciæ and tendons can be overcome by mechanical means, but the obstacle offered by the capsule itself is the chief one to be considered in the reposition, and the most important of all the obstacles is a narrow capsular isthmus. The ligamentum teres offers but little obstruction. He considers that the rudimentary acetabulum is not large enough to retain the head of the femur and for this reason the limb must be held for some time in an abducted position after correction, in order that the acetabulum may be moulded into the proper shape. It is necessary that the limb, after correction, should be held in what he calls the primary position, in order to keep the head next to the acetabulum.

But besides this, and more important, is what he calls the secondary position, which involves the throwing the weight of the body upon the head of the femur, by allowing the patient to walk in a required position which brings a strain upon the head of the femur and the rudimentary acetabulum. He considers that the bloodless operation is best performed between the ages of ten and three in single dislocation. The cure cannot be said to be established except after a thorough after treatment. In cases which are too old for reduction the writer recommends a combination of the bloody and unbloody method; that is, the reposition of the head by means of operation without deepening of the acetabulum, and the after treatment according to the principles of the bloodless method. He thinks that preparatory extension is unnecessary in young children; in older children this can be supplemented by subcutaneous tenotomy of the long muscles. In young children the reduction of the dislocation can take place by means of the hand without the help of apparatus, through extension and abduction of the flexed and inward twisted femur. In the more severe cases it is necessary to stretch the limb by using a wedge-shaped padded formed cushion under the trochanter as a fulcrum. The thigh is abducted to 90° gradually by lever movement and the head brought into place. Great care must be used in the employment of this maneuvre. After reduction the limb is best kept in a slightly abducted position, with the limb turned outward. The latter position is desirable in order, by pressure, to increase the strength of the anterior fibrous walls of the capsule, and to present a flat position forward. This apparatus should be worn for four or five months. The possibility of a reluxation backwards may be considered as avoided. When a middle position with flexion and abduction of the secondary position is reached the limb is placed in this position and the apparatus worn for five or six months, the apparatus consisting of a plaster bandage. In the first stage hyperextension is desirable. Active gymnastics are necessary in addition to the correction. In double dislocation the reduction of both hips should be done at the same time in young children.

Lorenz is of the opinion that, for a cure, treatment by means of fixation apparatus is necessary for two years after the reposition.

Kirmisson[1] reviews the subject as a whole. Lorenz earlier claimed his method (the bloodless reduction) as a radical one, but in 1898 recognized that in many cases as shown by the x-ray, his results, though good, were not a true reduction, but a transposition of the femoral head forward.

The list of complications (of all bloodless methods) is large. It includes many fractures of the femoral neck, epiphyseal separations, one fracture of the pubes, a gangrene of the thigh due to obliteration of the femoral vessels by the forward displaced head, and several paralyses of various sciatic branches, fortunately temporary.

As to results of the bloodless method, Lorenz has failed 15 times in 360 cases, and of 135 cases the radiographs of only 79 show anatomically satisfactory results. Hoffa has employed Lorenz's method in 64 cases (22 of these double). In all these the reduction has been successful, but of the 42 unilateral cases only 4 showed permanent reduction. In many others there was simply a transposition forward. In the bilateral cases the results even less good; never a permanent reduction of both hips; in 4 cases the reduction permanent on one side, transposition on the other; 3 times complete relapse of both; 15 times transposition on both sides with good results. Nineteen times Hoffa has tried Schede's methods. Of 13 unilateral cases he had 1 reluxation; 12 transpositions up and forward. In 6 bilaterals, 1 deluxation and 5 transpositions. Mikulicz's methods Hoffa tried 7 times, 4 cures, 3 improved. Hoffa treated with his own method 17 unilateral, with 9 cures and 8 transpositions; 3 double, 1 cure; 2 transpositions.

Petersen reports 161 cases from Schede's clinic (70 of them bilateral); real permanent reduction in 8 unilateral, in 2 double. Schede and Petersen have come back to Paci's point of view and hope usually only for amelioration — for transposition. Mikulicz, Heusner, Lange and Kummel have become skeptical of results. As things stand, the bloodless method is advisable hardly after ten years; after this, open operation (which has been too much given up). For much later cases subtrochanteric osteotomy often advisable and serviceable.

Kirmisson finishes by reviewing the benefits of fixation following traction, followed for several years and keeping the head forward near the normal position. The displacement is a gradual one favored by motion at the hip and greatly retarded by fixation. Kirmisson is inclined rather to regard forcible reduction as a last resort than as desirable.

Hoffa's[2] technique includes extension of leg, counter extension from the perineum; incision in front and above trochanter down and back, about 6 centimetres long; the gluteus maximus is drawn upward; the capsule incised with the limbs abducted; the anterior face of the capsule split to the pelvic insertion; dislocate the head; gouge out the new acetabulum; reduce; the wound is not sutured. Hoffa did the open operation 248 times; 10 deaths, *none* in the last 132. Concludes, always first try the bloodless reduction, if this fails then open operation; most favorable age is three to eight years. After treatment of massage and gymnastics is very important.

Broca and Monchet[3] have treated 38 cases of unilateral and 24 bilateral hip luxations at ages from twenty months to fourteen years. All cases treated exactly according to Lorenz's present methods. All cases above ten were failures. Of the 62 cases only 2 proved by the radiograph to be actual reductions. Almost always a transposition of the head forward toward the anterior spine. As to results 15 are called excellent, 25 satisfactory.

Doyen[4] thinks radical cure only by the open operation. Has devised a special borer to form the acetabulum — this he thinks the most important part of the operation. The actual reduction may need his special retraction hook to replace the head. After operation he abducts and rotates inward. May be necessary to correct rotation later by *supracondyloid* osteotomy of the femur.

POTT'S DISEASE.

Bradford[5] read a report on the subject defining somewhat closely the class of cases where any forcible

[1] Rev. d'orth., 1900, p. 289.

[2] Thirteenth International Congress, 1900.

[3] Loc. cit.

[4] Loc. cit.

[5] Loc. cit.

reduction is allowable and defining the aims of retentive and corrective treatment.

Rédard and Besançon have used forcible correction in selected cases with good results and apparent osseus repair in some, about one-quarter in half of the cases a fairly satisfactory result; in the remaining quarter the results were rather poor.

Broca and Monchet have forcibly reduced 40 cases. They do not believe in operating on cervical cases or cases with abscess or with lung complications. In 12 of the 40 correction not actually effected. Are ready to proscribe the operation in all but early cases. Many cases relapsed.

Ducroque [6] states that in correction of older deformities it is useless to attempt even if correction is possible. In 20 cases operated on two to four years ago the deformity has entirely relapsed. The *rédressement* has hardly any indications save in paraplegia.

Phocas has given up forcible correction for simple extension under chloroform. In 13 cases so treated 6 could not be reduced, 2 relapsed very early, 2 died, 6 had abscesses, only 1 remained definitely corrected. As a result is ready to give up *rédressement* in all its forms for immobilization.

Calot [7] has nothing to say for forcible reduction today, but much of dorsal decubitus in plaster apparatus and of correction by suspension, especially for paraplegic cases.

Chipault advocates suspension by the feet and application of plasters. Further correction than this he would confine to paraplegic cases.

Piéchaud definitely condems forcible correction. He has tried it and disbelieves in it and has come back to the use of the dorsal decubitus.

Menard and Guibal [8] have experimented on spines to produce experimental kyphosis in imitation of that of Pott's disease. Their results are best studied from the figures with which the article is richly supplied, but in general the experiments showed that, (1) in the cervical region destruction of the vertebral bodies is not accompanied by a *proportionate* kyphosis; this is owing to the support of the laminæ and transverse processes which come in contact — there is, however, a *total* shortening of the spine at this point, estimated at about one-half, a shortening without much definite kyphosis; (2) in the dorsal region there is no definite hindrance to inflexion except that of the ribs. In fine, the degree of kyphosis here *is* proportionate to the destruction of the vertebral bodies; (3) in the lumbar region the results are intermediate; there is some shortening (one-quarter the height). Up to a certain point the inflexion corresponds to the destruction, but less accurately than in the dorsal region.

Bouquet [9] reports a case of Pott's disease with abscess in which the dorsal decubitus was impossible from pain. The child was put on the belly, with traction from the legs and from a short corset. This kept up for four months and the abscesses healed. On getting up the child, which had previously had a marked kyphosis and a lateral deviation, was practically perfectly straight, and remained so for four months (apparently without apparatus — none is mentioned). Author thinks the child's effort to raise the head (it was a child of eleven years), had much to do with the correction.

[9] Loc. cit., 1900, p. 217.

ALTERATION OF THE INTERNAL ORGANS IN SCOLIOSIS AND KYPHOSIS.

Bachmann [10] has thoroughly investigated this subject. He has collected a scattered literature of the case. Out of 276 cases there was a total of 666 lesions of the organs of the circulation, with 164 diseases of the heart muscle and valvular lesion. A transverse position of the heart and an unusual position of the thoracic and abdominal organs, with the separation of the esophagus from the aorta, was noted in a number of cases. The causes of death in kyphoscoliosis is chiefly heart failure, and congestive bronchitis with hypostatic pneumonia and hypertrophy of the heart is common. Tuberculosis of the lung is not common in the severer grades of kyphoscoliosis.

Satterthwaite [11] has studied the displacements of the the heart in scoliosis. He is not disposed to exaggerate the importance of these, but has found displacements present, and moreover has seen prompt amelioration of cardiovascular symptoms as a result of amelioration of the deformity without other treatment.

Counsel's treatment by exercises was modelled on Roth's system.

ORTHOPEDIC CORSETS IN SCOLIOSIS.

Hussey,[12] in an interesting and thorough article on the disadvantages of the use of the corset in lateral curvature, claims that any corset is a disadvantage and increases the tendency to rotation and side deviation. This view is opposed by Vulpius, and by Schanz.[13]

Schanz [14] claims that the unsatisfactory nature of the treatment of lateral curvature lies in the lack of thoroughness in the method of treatment, and advises the forcible correction in severe cases, this correction treatment being carried out for four weeks. After this gymnastics and massage should be carefully carried out.

ACUTE OSTEOMYELITIS IN THE REGION OF THE HIP.

Bruns and Honsell [15] say this affection is not common, and the writers have collected 106 cases in the last forty years of the clinic in contrast with 500 cases which have been collected of osteomyelitis of the lower end of the femur. Of these, 12 patients were between one and five, 25 between five and ten, 43 between ten and fifteen, 23 between fifteen and twenty, 2 between twenty and twenty-five, and 1 twenty-six years of age. Males are more frequently affected than females. The affection may begin, and usually does, in the upper portion of the diaphysis. In some cases it is in the upper epiphysis and occasionally may be in the acetabulum. There is a tendency for the cartilage to protect invasion of the joint, but when the upper epiphysis is affected in the severer cases the cartilage may be perforated. This is frequently the case where the acetabulum is affected. More common is the affection of the upper end of the diaphysis, with a separation of the epiphysis of the head of the femur. The affection may, and usually does, cause suppuration and anchylosis. In the severer cases it causes subluxation; in many cases, however, this is not the case. There is less likeli-

[15] Beitr. zur klin. Chir., 1899, p. 41.

hood of shortening after this affection than after the tubercular affection, except in cases of spontaneous luxation. The onset is sudden and the patient is in a dangerous condition at first. After the onset the patient usually comes into a better condition, and improvement follows. The diagnosis between the osteomyelitic affection and the tubercular affection is usually easy, as the invasion of the former is usually acute. In the subacute forms, however, the diagnosis is not easy and must rest largely upon the bacteriological investigation.

Owen[16] gives a special article on osteomyelitis of the femoral neck. It is most common before twenty years. The symptoms are those of osteomyelitis in general, with addition of flexion and adduction of the hip. The prognosis depends on early operation; may be rapidly fatal. Four cases reported. One fatal, died of sepsis after operation. One recovered after long treatment. Two were resected with good functional result.

TUBERCULAR OSTEOMYELITIS OF THE SHAFT OF THE LONG BONE.

Kuttner[17] found only 6 cases of this affection among over 2,000. They are of two classes, the primary affections and the secondary, that is to say, those which extend from an inflamed joint. The primary are extremely rare; the anatomical appearance is varied, and consists either of circumscribed focus or a diffused process extending into the whole of the medullary cavity of the shaft. Either a tubercular bone abscess is formed or very rarely a condition like the spina ventosa of the short bones. The affection may extend to the epiphysis and joints. It usually attacks young children between the ages of two and six years, who as a rule are affected by multiple tuberculosis. A diagnosis is difficult on account of the resemblance to the process following acute osteomyelitis.

The secondary osteomyelitis is almost exclusively confined to the shoulder. In Bruns's clinic the cases were chiefly in adults, but the affection can also occur in children. Unlike ordinary osteomyelitis, the cartilage is not a complete protection from the invasion of the inflammatory process. The affection is a destructive one.

Ollier[18] adds one to his series of late autopsies, showing end results after subperiosteal elbow resection. This case is of especial interest in that it was performed on an adult for extensive, destructive tubercular disease and that during the eighteen years that had elapsed between operation and autopsy the patient had done hard and exhausting work as a vinedresser. The range of movement increased with increasing strength till fourteen years later flexion and extension were practically normal, supination two-thirds normal, pronation normal, the strength of the arm in extension over three-fourths that of the sound side. Seventeen years after the operation he had lost a few degrees of extension, but the joint was still firm and strong. The patient died eighteen years after the operation of a generalized sarcoma in the prevertebral region, primary in the clavicle or ribs apparently.

The autopsy showed extremely good reproduction of the olecranon, and of the V-shaped humeral end into which the forearm fitted. There was no joint cavity, but lacunæ in the uniting fibrous tissue and some formation of fibrocartilaginous plates, especially in the sigmoid cavity.

The case is interesting from its permanence so far as disease was concerned, from the remarkable return of motion with, nevertheless, a firm joint and a notable return of muscular function, even in the triceps.

Most interesting of all perhaps is the light it throws on the conditions necessary for a permanently mobile joint in this form of resection. For seventeen years the patient had subjected his arm to severe, often to excessive, use and the joint had remained supple; six months or less before death he had been unable to work, and in this time the range of extension had decreased from 70° to 25°. So here, as with resections of the older types, there is no joint formed, but a fibrous mass tending always to recontract unless forcibly prevented by use. The case cited shows how perfect may be the result so long, and only so long, as use is constant.

Hibbs[19] has studied the atrophic bone shortening in cases of hip-joint disease, and especially the tibial shortening. Fifty cases were measured. The shortening in both femur and tibia, about the same usually, may be over 3 centimetres each. Exists in 60% of the cases.

RESECTIONS IN SUPPURATIVE COXITIS.

Nelaton[20] reports in detail 2 cases of resection in a boy of fifteen and a woman of twenty-six years. The first, after two years of treatment with poor result, was subjected to resection. Persistent fistula; anchylosis not yet complete. Walks, but with a limp. The second case treated a year and a half with fair result — wound closed after five months. Shortening 3 centimetres. No anchylosis. The cases do not present a sufficiently long interval after operation to warrant so favorable a set of conclusions as the author draws.

The chief interest of the article is that the author definitely concludes that the best result to be hoped for in operation of cases even comparatively early is anchylosis in good position. Late excision gives results preferable to conservative treatment, but less good than the desired anchylosis.

TUBERCULAR OSTITIS OF PATELLA.

Gross[21] reports 4 cases. Age as often above as below twenty years. Symptoms are spontaneous pains day or night, pain on pressure, unevenness of surface of bone, movements little interfered with unless joint is invaded. The pathognomonic symptom is a prepatellar abscess of slow formation, much less mobile than the bursa. Puncture will settle all doubts. The treatment is removal of the disease, with or without resection of the patella, or opening the joint as occasion demands.

He considers 30 cases of primary tuberculosis of pate la gathered from the literature.

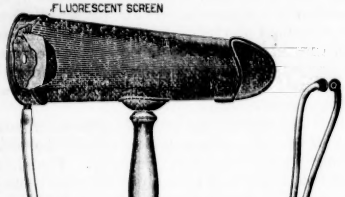
New Instrument.

A SMALLER SEEHEAR.

BY WILLIAM ROLLINS, BOSTON.

IN a larger form this instrument was described in the *Electrical Review* for February 8, 1899, and in other journals. The instrument contained two principles new in stethoscopes, one a sound chamber, the other a fluorescent screen in connection with such a sound chamber. The former has since been adopted in one of the stethoscopes in common use. The latter awaits recognition. There is an advantage in using both eyes and ears in studying the interior of



THE SEEHEAR.

the chest, therefore I illustrate here a simple form of the instrument. As I have designed x-light apparatus capable of yielding a powerful x-light under control in quality and intensity, the use of the instrument is not difficult. It is only necessary to use a tube of low resistance, varying the amount of x-light by regulating the current in the primary and the position of the secondary in the space of ether strain, to make the heart or lungs clearly visible to an untrained eye.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

HENRY F. HEWES, M.D., SECRETARY.

REGULAR meeting, Wednesday, December 19, 1900, DR. V. Y. BOWDITCH in the chair.

DR. J. L. GOODALE read a paper entitled

RETROPHARYNGEAL ABSCESS IN THE ADULT.[1]

DR. F. C. COBB read a paper entitled

PERITONSILLAR ABSCESS.[2]

[1] See page 108 of the Journal.
[2] See page 106 of the Journal.

DR. FARLOW: I have seen several cases of retropharyngeal abscess in the adult, but never of tubercular origin unless there was tuberculosis of the spine. Several years ago I was called to see a lady of about fifty, who complained of some soreness of the throat and difficulty in swallowing for a few days. I was much surprised to find a marked bulging of the posterior pharyngeal wall, with elastic, fluctuating feeling to the finger. There was no evidence of tubercular or specific disease and the cause of the trouble was not clear. There was no pulsation, no neoplasm, and it seemed to be a very unusual case of non-tubercular retropharyngeal abscess in the adult. I proposed to make an incision, but was not allowed to do so, and the case passed into other hands. I do not know the outcome.

There is a condition not very infrequently met with which, at first glance, might lead one to think of retropharyngeal abscess, and that is an asymmetrical position of the pharynx. If the pharynx is not directly in front of the vertebral column, the projecting vertebræ may give the impression of an inflammatory bulging, until the examining finger shows that the projecting side of the pharynx is hard and bony.

As regards peritonsillar abscess, I quite agree with Dr. Cobb in not considering a rheumatic origin well substantiated. I am always in the habit of looking about the tonsil and exploring the crypts, and especially the supratonsillar fossa, for some possible seat of infection. I have seen 2 cases recently in which the inflammation was behind the posterior pillar, a most unpleasant region in which to make the incision, especially when one bears in mind the possibility of meeting one of the large, abnormal ascending pharyngeal arteries, which are occasionally found in this situation. According to Dr. Moritz Schmidt, the abscess points in the anterior pillar in 98% of the cases, and in the posterior pillar in 2%. In order to prevent an early closure of the opening and to ensure a better evacuation of the pus, I pass a probe in various directions so as to open up the various pockets of pus, break the trabeculæ, etc., and then dilate the opening with a pair of strong forceps. This leaves a gaping wound which is much more likely to stay open than where only an incision is made. This is scarcely applicable, however, when the incision is in the posterior pillar.

A great difficulty in the treatment of many of these cases is the inability of the patient to open his mouth. I have seen 2 cases so severe that chloroform was given to get the mouth open, not only to make the diagnosis, but also to carry out the treatment. Some of the distress is caused by secretion behind the posterior pillar which is tenacious and hard for the patient to expectorate. A warm, alkaline solution sprayed gently through the nose helps the patient to rid himself of this mucus. A hot poultice to the neck is very soothing when pus is forming.

DR. KNIGHT: In regard to the first paper — "Retropharyngeal Abscess in the Adult" — I must say I have never seen what has been considered an idiopathic case. All the cases I have seen have been those in connection with disease of the vertebræ. The general practitioner is liable to mistake not only a congenital deformity of the vertebræ for an abscess, but also what may be the natural prominence. I have had a good many cases brought to me by practi-

tioners, thinking that they had something abnormal, possibly an abscess, which was nothing but the ordinary prominence of the vertebræ in the centre of the pharynx just behind the uvula.

In regard to the peritonsillar cases it seems to me very unfortunate that even in many modern textbooks on disease of the throat, even by specialists, they are still grouped as cases of tonsillitis, and the two topics more or less treated together. I think it is possible that infection, as Dr. Farlow states, may sometimes come from the tonsil, but peritonsillar abscess is not usually associated with acute tonsillitis, which has a clinical history of its own. Certainly in many cases the tonsils appear healthy.[3] Whether it is connected with any diathesis or not, rheumatic or other, is of course still a question. A very large number of observations made at different periods by all kinds of medical men seem rather to confirm this idea, and it is one's experience as he looks back that he sometimes finds an association between this condition and rheumatic conditions. I cannot think it is any evidence against its rheumatic nature that when suppuration has occurred and we have a peritonsillar abscess, antirheumatic treatment, so called, does not affect it. You would hardly expect it to, but whether in those patients who are subject to peritonsillar abscess we do not sometimes abort the thing is a question. Certainly where a patient has an attack of this kind once or twice in the year, and by the use of salicylates or bicarbonate of soda in huge doses, the attack seems to be avoided a good many times, one cannot help feeling that possibly diathesis has something to do with the condition, but the question of abortion of this, as of other diseases, of aborting pneumonia and aborting pleurisy, is always very doubtful, because you do not know what you might have had without treatment. If the condition is sure, if you are sure of an abscess, of course nothing is going to abort it.

In regard to the treatment of these cases, I think on the whole, perhaps, a patient is made more comfortable if he has the old antiphlogistic treatment in the beginning. Of course, nowadays, it is not customary to vomit and purge, etc., but purging and aconite, as suggested, do seem to me to make the patient more comfortable. Locally the use of hot water — particularly hot alkaline water — gives the greatest comfort in the removal of mucus from the patient's throat.

In regard to operation, another point comes up. Of course, I suppose everybody has incised a good many times without getting any pus. The question is whether that relieves the patient. It seems in the beginning to relieve. The bleeding seems to give some comfort, and it has been customary with some men to make a good many punctures for the sake of the relief. I think on the whole the patient is more uncomfortable in the end, with three or four punctures and the cicatrices, than if let alone, that is, if no pus is reached.

The question of prevention of recurrent attacks is a very important one. Of course all the ordinary hygienic means are to be established, but locally many physicians have claimed that excision of the tonsil lessens the chance of recurrence. I cannot help thinking that this idea originates largely in the confusion which I have spoken of between tonsillitis and peritonsillar abscess. Of course if the tonsils are very large they naturally should be excised, but if not large, whether excising the tonsil would make any difference in the origin of the peritonsillar abscess is, I think, doubtful as regards most cases. There is no question but that when a patient is subject to tonsillitis with swelling of the gland, even when the tonsil is small, an excision practised on the tonsil will prevent future attacks, but I doubt whether it would have anything to do with the peritonsillar cases except such as might be infected from the tonsil, as Dr. Farlow suggests.

The proclivity to the disease seems to me to lie in the peritonsillar connective tissue, and that while infection is not necessary from the tonsil or through it, it is more likely to come through than directly from it.[4]

DR. LANGMAID: It is rather singular that it remains for Dr. Goodale to give the first instance of retropharyngeal abscess without caries of the spine in which tubercle bacilli were found, but it seems to me that they might have been found in many other cases had one been as careful as Dr. Goodale was to examine the pus which came from the abscess. That formerly was almost never done and I imagine is rarely done now. With your permission, Mr. Chairman, I will read some notes of a case that comes under one of the headings that Dr. Goodale spoke of, namely, septic retropharyngeal abscess in an adult. It is so rare, at least in my experience, that I was very much interested in the case, and I thought it had some bearing upon the classification which Dr. Goodale read.

On July 10, 1900, Mrs. R., a young married woman, was seen in consultation. She had a history of previous attacks of tonsillar abscess. Had been ill with amygdalitis for one week. Both tonsils have been punctured, but no discharge of pus followed. The wounds on both tonsils are covered with a grayish-white membrane. A small patch of similar membrane is seen on the tip of the uvula. A culture taken during the first days of illness did not reveal the presence of diphtheritic bacilli. There is an external swelling on the right side of the neck. Temperature 103°, pulse 100. A poultice to the swelling of the neck and a gargle of permanganate of potash were advised. A culture from the membrane showed staphylococcus, but no Klebs-Löffler bacilli.

On July 11th, temperature 100⅗°; wounds much cleaner, but external swelling greater.

On July 16th I was again asked to see the patient. The external swelling had increased. The right tonsil was pushed forward. The wounds of previous incision had healed and there was no membrane. There was an extensive fluctuating swelling on the posterior wall of the pharynx, confined to the right side. Free incision into the swelling gave exit to a large amount of pus, which continued to flow for forty-eight hours. Complete recovery followed. This post-pharyngeal abscess was caused, I have no doubt, by infection from the puncture of the tonsil.

It seemed to me when I heard Dr. Goodale's classification that that came very well under the heading of a septic retropharyngeal abscess.

[3] Of course, as Dr. Goodale suggests, infection may take place through a healthy tonsil.

[4] The day after this occasion a lady of twenty-four years came into my office, who had formerly been very subject to peritonsillar abscess. Her tonsils had been very large and they were thoroughly excised last winter in another city (the remaining tonsillar tissue was not dug out), and the following spring she had the first peritonsillar abscess in six years. This experience recalls Swain's suggestion that the function of the faucial tonsil may be to destroy pathogenic germs entering the mouth with the ingesta.

Everything has been said, so far as I know, with regard to the causation of retropharyngeal abscess, but it is possible, it seems to me, that a lesson may be learned from this case with regard to early puncture of the tonsil. For some years I have refused to puncture the tonsil in the first days of amygdalitis. The patient demands it, and the tendency is to put a knife in somewhere and draw a little blood. Temporarily the swelling is decreased and the patient feels better for a time, but it is possible that wounds so made may become infected. That it is rare we know, but it is possible. It seems to me, so far as my own experience goes, it is not very common that one needs to explore very much to get pus. When it is time, ordinarily, some fluctuating point is found and the abscess can be evacuated, but I can imagine cases in which it would be allowable to go upon dangerous ground to relieve the very great swelling, dyspnea or apnea which might ensue.

Dr. Knight has spoken about the recurrence of tonsillitis. It has always been to me a very singular thing how regularly some people have an inflammation of the tonsil, even more than that, a peritonsillar abscess, and is it not for that reason perhaps that a dyscrasia is suspected? For a good many years, in those who had recurring attacks at about the same season of the year, I have tried to do what I could in the way of advice that the patient might avoid the attack by means of treatment of some condition which he recognized as preceding or accompanying these attacks. Whether they have or not it is impossible to say, my experience is so small.

DR. COOLIDGE: Retropharyngeal abscess in the adult is certainly a comparatively rare condition. I do not think I have seen a case for four or five years in a large out-patient clinic. I think that what Dr. Knight said about the lack of good description of peritonsillar abscess in our textbooks is very noticeable. There should be, but there is not in these books a detailed description of the anatomy of the tonsillar region. The anatomy is quite complicated and almost nothing is said about it. Several years ago His described the supratonsillar fossa and also the other structures in connection with it, especially the plica tonsillaris, a fold of membrane which can be demonstrated in almost every throat in which the tonsils are enlarged. This plica varies very much indeed in different throats. Sometimes it is very large and includes a large part of the tonsil as if in a sling, so that, although the tonsils are large, the crypts are seen only over a small area. In other cases it is small. Three or four years ago Paterson and, I think, Killian called attention to this supratonsillar fossa as a possible source of a good many morbid conditions of the tonsils.

We have all noticed the differences in the appearance of large tonsils. Sometimes we see a pair of tonsils which project into the throat, free from adhesions, with the openings of the crypts visible over almost the whole surface of the tonsil, in which the guillotine or wire snare will embrace and enucleate the whole organ. In another case the tonsils may be quite as large, but so bound down and adherent to the anterior pillar in front and the posterior pillar behind that it is utterly impossible to get a guillotine around them on account of these adhesions. To remove them they must be dissected out or attacked with the tonsillar punch or galvanocautery. This same difference we find in smaller tonsils, that is, the difference in adhesions to the surrounding structures. In case of peritonsillar abscess we almost always find a tonsil pretty firmly adherent to these different structures in the neighborhood.

As to the etiology of peritonsillar abscess, it seems to me that we have seldom any evidence of rheumatic or other general constitutional condition as a cause. As far as I have been able to learn from patients, we find no more history of rheumatism in cases of peritonsillar abscess than in anybody else, neither do many cases markedly rheumatic have attacks of peritonsillar abscess. But this we notice: One patient will have recurring peritonsillar abscess on the right side, perhaps twice a year or at irregular intervals, and the left side never be affected. It is impossible to believe that one side has any different diathesis from the other. It seems to me that this history, which is extremely common, points to some anatomical defect or local condition as the cause of the recurring abscess rather than any general conditions. The local cause it is impossible in most cases to make out. Sometimes the tonsil is large, sometimes small, adherent and hard, sometimes not. Generally the tonsil is pretty well bound down to neighboring structures.

As to the question of abortion of peritonsillar abscess, a certain number of cases — I am inclined to think they are larger in proportion to the total than we perhaps think, because they do not all apply to us for treatment — will undoubtedly spring a leak, as it were, after the suppurative process has been going on for a few days. A case will start in with pain on one side of the throat. The patient knows what it is, for he has laid up for days with peritonsillar abscesses in the past. It gets worse for a few days and then begins to get better. Every now and then on inspection we find a drop of pus oozing out somewhere, which in the course of another day or two would entirely empty the abscess.

The study of the anatomy of this part is extremely important, and the knowledge of the probable position of pus will help us to get at it. I feel that we do not yet know enough about the probable seat of pus to attack the right place as often as we ought to. These cases are hard to examine. The patient perhaps cannot open his mouth, everything done is painful, and it is not possible to study the part carefully. I have noticed that after an abscess has been opened through the anterior pillar and pus evacuated, a probe with a sharp curve passed in the direction of the supratonsillar fossa can often without much force be pushed through into the supratonsillar fossa. The discomfort to the patient is often less than the original puncture in the pillar. Abscesses rarely open spontaneously through the anterior pillar, almost always the pus comes out somewhere around the tonsil.

As to the prevention of peritonsillar abscess. I believe that almost all cases are due solely to some anatomical fault in the tonsil or neighborhood of the tonsil, some spot perhaps becomes infected and the natural outlet closed so that the septic process works back. Prevention seems to me to consist in getting rid if possible of that anatomical fault. The first thing surely is to get rid of the tonsil, and although I have not been able to follow many cases to ultimate conclusions I feel if we can clear out the whole tonsillar region of all glandular masses that we have done the

best for preventing the return of peritonsillitis. We may not at first in dissecting come across the place where infection enters.

Dr. J. Payson Clark: I was very much interested in this case of retropharyngeal abscess, which we had at the Massachusetts Hospital throat clinic last June. One or two points about it, as I remember the case, I think Dr. Goodale did not perhaps sufficiently emphasize. The case presented many of the characteristics of a cold abscess. There was no pain or other evidence of a local inflammatory process, but the abscess had the appearance of a hemispherical tumor, rising abruptly from the surrounding pharyngeal wall and differing in that way from the ordinary retropharyngeal abscess we see in children, which usually appears as a pushing forward of half or all the posterior wall. It stood out as a distinct localized tumor, and I should have said to one side of the pharynx rather than involving the whole posterior pharynx. Dr. Goodale took charge of the examination of the pus and I am glad that he has reported the case.

As to the rarity of these cases, I took the trouble to look over the books of the throat department, or rather our reports for the past twelve years since January, 1889, and I find there have been during that time 18 cases diagnosed as retropharyngeal abscess. Of these 6 were in adults, 5 men and 1 woman. In one of these adult cases the inflammation was spoken of as phlegmonous and in another it was thought to be a broken down gumma.

I have very little to add to the discussion of Dr. Cobb's paper. As regards treatment, I have opened the peritonsillar abscess in all the ways spoken of, by going between the anterior pillar and tonsil, going through the tonsil itself, and going through the anterior pillar; also in those cases, which I think are quite rare, where the abscess is in the posterior pillar, opening that. The first two methods are in every way the most satisfactory if the abscess cavity can be reached by them. I should like to emphasize what Dr. Farlow said about going into the abscess cavity with a probe and breaking up any little trabeculæ that may be there or opening up any separated pockets, and also the use of the forceps to dilate the opening. In this connection I wish to say that I think the thorough evacuation of the abscess cavity at the time the opening is made is very important. If one gets rid of all the pus one can, I think there is much less likelihood of a refilling of the abscess cavity, which does sometimes occur in spite of all that one can do.

Dr. Cheever: I have not seen any retropharyngeal abscesses except in connection with caries of the spine. I have seen but few, and they have always been cold abscesses. I think relief is given by opening, though I doubt if they close very soon, as almost any cold abscess connected with caries of bone results in a long-continued sinus. Psoas and lumbar abscesses are intolerably long; they sometimes close by gradual inspissation of the pus and shrinking up after a while, sometimes they do not. The retropharyngeal abscesses I have seen have been painless, and interfered mechanically with swallowing.

With regard to the abscess about the tonsil, the most interesting question to me is, what can be done, if anything can be done, to prevent recurrence. There are certain persons who have them over and over again. I have had as a patient a good many years a young man who rarely escapes a winter. Sometimes he goes two years, but generally has one every year when the seasons are breaking up towards spring. The last time he had follicular tonsillitis combined with the abscess, which I think is rare. The tonsillitis did not get better, the patches became large; I became alarmed about him; took a culture from the throat, and told him I might have to remove him from his hotel. The culture was negative, and the next day the whole region had swollen up and an abscess rapidly developed; and then the peculiar grayish look about the tonsils and palate, as well as the follicular points, gradually went away after evacuating the abscess. All my professional life I have had the care of a strong Irishman and have seen him frequently. During many years he had peritonsillar abscesses. I have opened a great many. He had no other sickness; never has been sick. I did not succeed in preventing them at all, but he came one day and said he had found a way of stopping them, and certainly it did seem to have a good deal of effect; not by any constitutional treatment, but local treatment externally by rapid blistering on the outside of the neck whenever he felt any symptom arise. This was followed by relief and no abscess. Of course it is always open to the doubt whether the abscess was about to form, but he was quite confident that he averted them. At any rate he went several years without any under this treatment. This treatment was harsh. He was in the habit of tying the throat up with kerosene oil, and the blistering was rapid and intense. As he grew older he ceased to have the attacks. He is now a man of perhaps sixty years old, and has not had any since he was forty-five or fifty. I am inclined to think the progress of age gradually does away with the tendency to inflammations of the cellular tissue. I have always felt great anxiety about these peritonsillar abscesses with regard to the nutrition of the patients, and with regard to affording them some comfort. They cannot swallow and cannot sleep. I have usually been afraid to give opium, and I have not had very great luck with cocaine; although sometimes if you paint the throat with a solution of cocaine, it seems as if they could drink a glass of milk afterwards with comparative ease.

In old times this affection was called quinsy, and you find in the old books as far back as the time of Cullen, and others, accounts of double quinsy followed by death. I do not remember to have heard of a death in this neighborhood, but there are very well authenticated cases in the old books where a double abscess has been followed by death, probably due to suffocation, and before the days of tracheotomy. As Dr. Knight says, I think these abscesses are benefited by saline cathartics. I have often been tempted to put leeches on the outside of the throat. I have seen other inflammations of the throat, threatening edema of the glottis, aborted by copious leeching.

Dr. Farlow: With reference to the lessening tendency to peritonsillar inflammation as patients get older, it is to be borne in mind that after the age of thirty-five or forty the tonsils naturally atrophy and become more fibrous, so that there is less likelihood of the crypts containing cheesy masses and germs which may act to start up a peritonsillar inflammation.

With reference to excision of the tonsil to prevent a recurrence of the inflammation, a mere removal of a portion of the tonsil, even down to the anterior pillar, may be of no great value. The diseased tonsillar tissue, the deep-seated crypts, should be thoroughly removed. This may be no easy matter and is not so well done with a guillotine as with a punch or some similar instrument, which can dig out the tonsil behind and between the pillars.

I have had much better success in preventing recurrence in this way than by the use of antirheumatic or other internal treatment.

DR. E. A. CODMAN: I have brought two x-rays which may perhaps interest the gentlemen in regard to the diagnosis of retropharyngeal abscess. One shows the side of the normal neck with the cervical vertebræ and outline of the pharyngeal wall; the other shows a case of cervical caries with the outline of the pharyngeal wall displaced by a retropharyngeal abscess or mass of inflammatory tissue.

DR. KNIGHT: I should like to ask if Dr. Coolidge would give us to understand that he has had a good many cases of recurrent form of peritonsillar abscess occurring in young subjects in whom you would have every reason to expect the continued recurrence, but in whom the attacks had entirely ceased after the removal of the tonsillar tissue?

DR. COOLIDGE: These cases are very hard to follow. They generally do not come back unless there is something the matter with them. I know of a few cases who have been free from it for some time after the digging out of the tonsil who before that had more or less frequent recurrences.

DR. KNIGHT: I would like to ask Dr. Coolidge if he feels that all cases originate from the tonsil?

DR. COOLIDGE: Not necessarily from the tonsil itself, but from the immediate neighborhood, some septic process between the pillars.

DR. H. F. R. WATTS: I have not heard it mentioned this evening whether or not it is common for abscess of the neck to occur in connection with peritonsillar abscess. I want to speak of a case I saw some months ago. A man who was not in the habit of having peritonsillar abscess came with a beginning one. There was not a fluctuating tumor, but there was the characteristic pain and edema of the pillars. I incised directly through the tonsillar substance. The tonsillar substance was fibrous and brawny. At a depth of about one-half inch I reached pus. It discharged a few days and he was better. He ceased to come back for about a week, then came and said it had stopped discharging in the throat a day or two after I last saw him, and he then began to have a swelling in the neck. He had a large abscess, directly s bcutaneous, over the sternomastoid and extending a ound to the median line and pretty nearly to the sternoclavicular notch. This was opened and a large quantity of exceedingly foul pus discharged. The whole thing kept him laid up about a month.

DR. GOODALE: I wish to say a word or two in regard to the etiology of these two forms of abscess. About three years ago I did some work on the power of the tonsil to absorb foreign substances in a state of minute subdivision when brought in contact with the walls of the crypts, and I found they went in very readily. I was urged by some pathologists to repeat the experiments, using harmless bacteria, but I thought that such an investigation would probably be misinterpreted by the laity and did not do it. I have just seen in the *Italian Archives of Laryngology* for May, 1900, that this has been done in Italy. The bacillus prodigiosus was brought in contact with the walls of the crypts of the tonsils, and made its way in very readily, not only into the interfollicular spaces, but into the interior of the follicles. On dogs the experiment was tried with virulent streptococci which penetrated even farther, that is, got into the extratonsillar lymph spaces immediately external to the capsule of the tonsil. It seems to me that these results may possibly answer Dr. Knight's objection to the idea of a tonsillar origin of peritonsillar abscess. I understood him to say that very often the abscess occurred without previous tonsillar inflammation. As has been shown here, virulent streptococci can make their way through the tonsil, apparently without giving rise to inflammation into the extratonsillar tissues, in which situation they may produce the abscess under discussion. A similar penetration of the lymphoid tissues of the fauces or pharynx by tubercle bacilli would explain the development of a tubercular retropharyngeal lymphadenitis in the absence of spinal caries.

DR. COBB: One object in reading this paper was in order to show that the puncture in the point of election through the anterior pillar has not in my experience been found very satisfactory. I am convinced that if the pus happens to be near the surface of the anterior pillar the point of election is the most satisfactory place, but if the pus is at all deep it seems to me it is not.

With regard to prevention I have said very little, but it has seemed to me in the few cases we have had a chance to watch at the hospital, in which the tonsil was as thoroughly removed as possible by punches, etc., used between the pillars as far as we could get, that the result rather moderated the number of abscesses, but did not stop them entirely.

Dr. Coolidge spoke of adhesions between the tonsil and the pillars being almost always present in these cases. It seems to me that that is quite true, and yet it is only this morning that we had a case of recurrent peritonsillar abscess not in an acute stage which had very large tonsils, and I think Dr. Coolidge will recollect we took them out with a snare, and the surface was absolutely smooth and glistening and without any adhesions. Removal of the tonsil by the usual method is not preventive of abscesses, but enucleation offers the best chance for success.

THE AMERICAN PHYSIOLOGICAL SOCIETY.

THIRTEENTH ANNUAL MEETING, HELD IN THE PHYSIOLOGICAL LABORATORY OF JOHNS HOPKINS UNIVERSITY, BALTIMORE, MD., DECEMBER 27 AND 28, 1900.

(Concluded from No. 4, p. 93.)

SECOND DAY.

FURTHER OBSERVATIONS ON EPINEPHRIN.

THIS paper by DR. J. J. ABEL was read by DR. R. HUNT.

A recent paper by Moore and Purington criticises the conclusions drawn by Professor Abel from his experiments on epinephrin, on the ground that the purified epinephrin compounds prepared by Abel from the

suprarenals do not show physiological activity proportionate to that exhibited by crude extracts of the glands. In this report it is shown that these preparations of epinephrin have a much greater effect on blood pressure than do the so-called "crude extracts" used by Moore.

The extracts used by Moore, however, were not crude, since the coagulable proteids and substances precipitable by lead acetate had been removed. Furthermore the injection of 5.7 millionths of a gramme per kilogramme of dog's body weight is found to give a rise in blood pressure equivalent to that obtained by Moore after injection of 24–108 millionths of a gramme of "crude extract." The minimal amount of "crude extract" necessary to produce a rise in blood pressure is, according to Moore, 1.2 millionths of a gramme, while the same effect may be accomplished by .45 millionths of a gramme of the pure epinephrin.

The fall of pressure which Moore observed when extremely dilute extracts were used is probably due to impurity. Attention is also called to the fact that if the rate of injection be too rapid, a rise of pressure may result from the injection alone.

It is also found that epinephrin solutions on standing become inactive, as the result probably of rearrangement of the molecular constitution.

FURTHER INVESTIGATIONS ON THE BLOOD-PRESSURE-LOWERING BODIES IN THE SUPRARENALS.

This paper was read by DR. R. HUNT. The earlier investigations by Dr. Hunt have shown that along with the blood-pressure-raising substance in the suprarenals, there exists a substance which lowers blood pressure and which may be separated from the former by treatment with benzoyl chloride. Last year he suggested that this substance might be choline. It is now shown that, while choline is contained in these preparations, another body is present which, unlike choline, forms a compound with mercuric chloride insoluble in cold water. It also differs from choline in giving a fall of blood pressure when injected into an animal already treated with atropine. The substance yields choline on decomposition. It may therefore consist of a glycerophosphate of choline arising from the breaking down of lecithins or jecorin. That it can be neither of these substances is shown by its insolubility in alcohol and ether. A substance which possesses the same properties is found to exist in brain extracts containing large quantities of the decomposition products of lecithin and jecorin. The toxicity of this substance is much greater than that of choline.

An indication of its possible pathological significance lies in the suggestion that it may be the precursor of the choline which is to be found in the cerebrospinal fluid in cases of general paralysis.

PHYSIOLOGICAL STUDIES ON THE BLOOD TAKEN FROM ANIMALS DEPRIVED OF THE ADRENALS.

DR. I. LEVIN read this paper by title.

DRS. L. B. MENDEL and E. C. SCHNEIDER presented a paper entitled

FURTHER EXPERIMENTS ON THE EXCRETION OF KYNURENIC ACID.

Jaffe's observation, that the excretion of kynurenic acid is diminished by feeding intestinal antiseptics, has led him to the belief that this substance, which is normally present in dog's urine, owes its origin to the formation of quinoline in the intestine as the result of putrefactive processes. The feeding of iodoform, however, does not have this effect. The probability is therefore suggested that kynurenic acid arises from the profound cleavage of proteid either as the result of digestive decomposition or of starvation.

In a number of experiments on fasting dogs, kynurenic acid was invariably found in the urine. Baumann's experiment, showing that after prolonged starvation, accompanied by the administration of calomel, kynurenic acid is still eliminated, was successfully repeated. This treatment, however, causes complete disappearance of all traces of intestinal putrefaction — that is, combined sulphuric acid — in the urine.

In phosphorus poisoning it is found that the increase in the amount of kynurenic acid excreted runs parallel with the increased katabolism of proteid. Observations on its elimination after removal of the spleen show that that organ plays no part in its formation.

Experiments were also made which show that the decrease in excretion of kynurenic acid which follows feeding of thymus glands is not due to the antiseptic action of nucleic acid, as Jaffe supposed, but to the fact that the decomposition of the proteid of the thymus does not yield kynurenic acid, that they behave in this respect like gelatine, chondrin and elastin.

DOES MUSCLE CONTAIN MUCIN?

This report was read by DRS. G. A. FRIED and W. J. GIES. It is designed to show something of the nature of the substance separated from muscle connective tissue by Schepilewsky and called by him mucin, but which has recently been found by Goodman to consist neither of mucin nor nucleoproteid, but of a substance comparable to von Holmgren's "stroma substance."

Experiments show that extraction of muscle connective tissue with lime water or baryta water separates a substance which is precipitated on neutralization or faint acidification, but which, unlike mucin, is soluble in a weak excess of acid. Further extraction with 5% solutions of NaOH or KOH of the residue left after such treatment yields a substance which is also precipitated by neutralization but which dissolves in a slight excess of acid. Analysis of these products shows that they correspond closely to the substances separated by Schepilewsky and by Goodman, and probably consist of alkali albuminate formed by the action of the extractive fluids.

The results also show that the presence of mucin in muscle cannot be determined by such methods as have thus far been employed.

DRS. A. N. RICHARDS and W. J. GIES contributed a paper entitled

METHODS OF PREPARING ELASTIN, WITH SOME FACTS REGARDING LIGAMENT MUCIN.

The presence of a mucin-like substance in ligament was reported by these observers a year ago. Closer study of this body proves that it is identical with mucin in all its properties. The average of analyses of five preparations shows that it contains 13.4% of nitrogen, and 1.6% of sulphur, of which 1.06% exists in ethereal combination.

The question was also studied as to whether the approved method for the preparation of elastin from

ligament is adequate for the removal of mucin and coagulable proteids. Three preparations of elastin were made, in which the finely divided ligament was subjected to thorough preliminary extractions with lime water and distilled water for the removal of these substances. In four other preparations this treatment was omitted. To determine the presence of mucin and coagulable proteids the final products were analyzed for sulphur. The preparations from which these substances had not been removed contained .2% of sulphur, a portion of which is easily split off as K_2S by boiling with KOH; while the sulphur in the elastin which had not been subjected to the preliminary extractions amounted to .15%, all of which is firmly combined. These figures include the sulphur of the ash, which amounted in all preparations to .11%.

Data were also given regarding the distribution of nitrogen in the decomposition products of elastin. Decompositions according to Schultze's method were made on three samples of elastin with closely agreeing results. The average of these results shows that 2% of the total nitrogen is split off in the form of ammonia, 2.8% as organic bases, namely, arginin, lysin and histidin, and 95.4% as amido acids. These figures support the assertion of Kossel and Kutscher in opposition to Bergh and Hedin, that arginin and lysin may be obtained on decomposition of elastin.

ON THE OCCURRENCE ON LIPASE IN THE BODY, AND ITS REVERSIBLE ACTION.

DR. A. S. LOEVENHART read this paper by invitation. To determine the presence of lipase the hydrolysis of ethyl butyrate into ethyl alcohol and butyric acid is employed. On examination of the various tissues of the body, lipase was found to be present in many, the relative amounts being represented by the following table:

Pancreas	1
Liver	2.93
Intestinal mucosa	.75
Kidney	.50
Submaxillary glands	.38

The suggestion is offered that the utilization of the body fat during inanition is brought about through the action of this enzyme, the fat being hydrolyzed by lipase and so transferred to the blood and lymph.

The fact that maltose has been shown to possess a reversible action, being capable of transforming glucose into maltose, as well as maltose into glucose, has led the author to the study of the effect of lipase on solutions containing mixtures of ethyl, alcohol and butyric acid. It is found to have a decided action on these substances, transforming them into the neutral ethyl butyrate. The extent of its action in this respect is dependent on the relative amounts of these three substances in solution; its activity ceases when equilibrium is reached.

The application of these observations to the other enzymes may lead to most important results regarding their action. It is possible that the glycolytic function of the tissues is due simply to a reversal of the process of glycogenesis.

DRS. WALTER JONES and JOHN AUER presented a paper

ON THE OXIDATION OF NATIVE PIGMENTS.

The black pigment from the horse's tail was dissolved in very dilute caustic soda and a 2% solution of potassium permanganate added in successive portions until a further addition would presumably have imparted a permanent pink tinge to the solution. The solution was then acidified strongly with HCl and treated with barium chloride. After filtering off the precipitate formed, the amber-colored filtrate was nearly neutralized with caustic soda, the resulting bulky precipitate being allowed to stand some days in contact with the liquid. Part of this precipitate is light and flocculent, while another part is heavy and crystalline, so that an easy separation of the two substances was possible.

The flocculent portion was shown to consist of a series of barium salts of varying color and solubility in dilute HCl, while the granular portion was found by analysis and chemical reactions to be a mixture of oxalic and malonic acids. These substances obtained in relatively large quantity undoubtedly represent largely the molecule of the original pigment.

The work indicates that the benzene nucleus plays a much less important part in the pigment molecule than was formerly supposed, and that the essential part of this molecule is probably an unsaturated fatty acid derivative.

DR. L. B. MENDEL gave some

OBSERVATIONS ON THE PRODUCTS OF PAPAIN AND BROMELIN PROTEOLYSIS.

The exact nature of the products formed by the action of enzymes of vegetable origin have not received sufficient study to enable us to tell whether one or several types exist. For this reason the author has investigated papain, the proteolytic enzyme of the *Carica papaya*, which has usually been regarded to be closely related in its action to trypsin.

It is found that papain preparations show proteolytic activity in both alkaline and slightly acid media. The primary products of proteolysis, carefully studied in the case of casein, correspond quite closely with those obtained by F. Alexander from peptic digestion. Leucin, tyrosin and tryptophan were not detected in any digestion where the influence of bacteria or bacterial enzymes was excluded.

These observations indicate that papain differs from known proteolytic enzymes of animal origin, and also from vegetable enzymes like bromelin, which readily forms leucin, tyrosin and tryptophan even in acid media.

ANALYSIS OF SOME NUCLEIC ACIDS.

DR. P. A. LEVENE read this paper. The older methods for the separation of nucleic acids from tissues are very varied and each is applicable to only one tissue. Accurate comparison of the different nucleic acids is therefore impossible. The method devised by the author and published by him last year is applicable to many tissues and so affords a basis of comparison.

Paranucleic acid from the egg yolk (vitellinic acid) made by this method agrees very closely with that from codfish eggs (ichtulinic acid), as the following figures show:

Vitellinic acid	C 32.31, H 5.58, N 13.13, P 9.38
Ichtulinic acid	C 32.56, H 6.00, N 14.00, P 10.34

Nucleic acid, prepared from the pancreas by this method, was also analyzed. The figures obtained differ from those obtained by Bang on his so-called guanylic acid from this gland, but agree very closely

with Schiemedeberg's analysis of nucleic acid from salmon sperm, and Osborne's figures on the nucleic acid from the wheat embryo.

This nucleic acid from the pancreas conforms to all the ordinary solubilities of nucleic acid and on its decomposition yields guanin and adenin. Bang's guanylic acid, on the contrary, possessed peculiar solubilities and only guanin was found after decomposition.

These facts give positive value to Dr. Levene's work, since they show that a body belonging to the ordinary type of nucleic acids may be separated from the pancreas, and give further proof that no form of nucleic acid is to be distinguished by yielding only one of the nuclein bases on decomposition.

Analysis of the nucleic acid from the bacillus tuberculosis showed that it contained 29% of phosphorus, the largest amount yet obtained in any nucleic acid.

The interesting observation was also made that large amounts of glycogen are to be found in the bacillus tuberculosis as well as in the pancreas.

A FURTHER STUDY OF THE GLYCOPROTEID IN BONE.

DRS. P. B. HAWK and W. J. GIES read this paper. This constituent of bone discovered by Dr. Gies, and designated by him as osseomucoid, has been subjected to a closer study with the following results. Analysis of many preparations show slightly varying results. The analysis of their purest preparation, however, gives the following composition:

C 46.41, H 6.76, N 12.08, S 2.04, O 32.71, S as ethereal sulphate 1.08.

The composition of Mörner's chondromucoid from cartilage is as follows:

C 47.30, H 6.42, N 12.58, S 2.42, O 31.28, S as ethereal sulphate 1.72.

Comparison of these figures shows that osseomucoid contains more hydrogen and oxygen than chondromucoid, and correspondingly less of the other elements; a relation which may have much morphological as well as physiological significance.

DRS. J. E. KIRKWOOD and W. J. GIES read a paper on

CHANGES IN THE COMPOSITION OF THE COCOANUT DURING GERMINATION.

In studying the germination of the cocoanut, the fresh nuts were kept at a tropical temperature on moist earth for one year. At the end of this time a stout plumule had appeared, about two feet in height, and a number of roots had pushed through the softened outer husk and had taken hold in the soil. The milk cavity of the ovule was completely filled with the fully developed cotyledon, which had absorbed a large portion of the endosperm. The nuts were in this condition when used for analysis.

Considerable quantities of a diastatic ferment and traces of a proteolytic ferment were found in the cotyledon. No cellulose-dissolving or fat-splitting enzymes have yet been detected.

Interesting data were presented, representing a large number of analyses, to show the relative distribution of water, solids, inorganic matter, and nitrogen in the roots, stem, leaves, cotyledon and endosperm of the germinated as compared with the ungerminated nut.

A NOTE ON THE USE OF A SATURATED SOLUTION OF MAGNESIUM SULPHATE FOR PREVENTING THE COAGULATION OF BLOOD IN BLOOD-PRESSURE EXPERIMENTS.

THE PHYSIOLOGICAL ACTION OF THREE POISONOUS MUSHROOMS, AMANITA MUSCARIA, A. BULBOSA OR VERNA, AND A. PHALLOIDES.

DR. W. S. CARTER read the above papers by title.

At a business meeting held at the close of the session on Thursday morning, the following were elected to membership: Prof. F. G. Novy, University of Michigan; Dr. I. Levin, New York City; Dr. A. N. Richards, Columbia University; Prof. G. H. Parker, Harvard University; Dr. Yandell Henderson, Yale University; Dr. Horst Oertel, New York University and Bellevue Hospital Medical College; Dr. S. I. Franz, Harvard University; Dr. Holmes C. Jackson, Yale University; Dr. R. S. Woodworth, New York Hospital and Bellevue Hospital Medical College; Prof. C. W. Greene, University of Missouri; Dr. P. M. Dawson, Johns Hopkins University; Prof. C. A. Herter, New York University and Bellevue Hospital Medical College; Dr. A. J. Wakeman, New York City; Dr. J. T. Halsey, McGill University; Dr. W. H. Parker, Harvard University; Dr. W. B. Cannon, Harvard University.

Recent Literature.

The Present Position of the Treatment of Simple Fracture of the Limbs. By WILLIAM H. BENNETT, F.R.C.S., Senior Surgeon to St. George's Hospital, etc. London, New York and Bombay: Longmans, Green & Co. 1900.

This brochure of 41 pages is a reprint,[1] after revision, of an address delivered by its author in opening a discussion at the meeting of the British Medical Association of August, 1900. It is the result of an analysis of data furnished by three hundred selected surgeons of London, Ireland, Scotland and the Provinces. The subject of early movement in the treatment of fractures; the operative treatment of simple fractures of long bones, the patella, and olecranon; the disability resulting from fractures, and the ambulatory treatment of fractures are in turn discussed. Finally the writer's conclusions are concisely stated.

In an appendix is presented a summary of the data from which Mr. Bennett has written his monograph. The surgeons from whom they were obtained are all members of the senior staffs of hospitals, having not less than one hundred beds, or practitioners doing extensive work among coal miners or sailors. The data have been tabulated in various ways. The monograph is well written. It is an interesting discussion of an important subject. It is valuable on account of its statistical information culled from such a wide field, and the manner in which it has been considered and tabulated. It represents the results of thorough, careful, painstaking investigation (except perhaps as regards ambulatory treatment). It is a contribution of merit and one deserving of study.

[1] British Medical Journal, October 7, 1900.

On the Use of Massage and Early Passive Movements in Recent Fractures and other Common Surgical Injuries, and the Treatment of Internal Derangements of the Knee Joint. By WILLIAM H. BENNETT, F.R.C.S., Senior Surgeon to St. George's Hospital, etc. Pp. 97, with 12 illustrations. London, New York and Bombay: Longmans, Green & Co. 1900.

This little book comprises three clinical lectures delivered by the author at St. George's Hospital, London, and afterwards published in the *Lancet*. The publication of the work in its present form has been postponed till now in order that more extended clinical observations might be made by the writer, especially with regard to the "internal derangements of the knee." His idea is that early massage and passive movement properly applied in selected cases is a valuable method of treatment and will often relieve muscular spasm and pain, and prevent complication resulting in nerve irritation and impaired motion. He makes a forcible plea for its use.

His argument is logical and his illustrations interesting and striking. His work shows extended clinical experience, also close study of detail and careful observation. His method is perhaps most startling as applied to the treatment of fractures of the olecranon and patella. His statements and results present ideas and suggestions so radically different from those commonly adopted that the reader's attention is aroused. As he turns the pages facts and ideas therein presented cause him to consider seriously the present routine treatment of fractures.

The chapter on the internal derangements of the knee is written after the clinical observation and study of 250 successive cases. It is the most interesting and valuable contribution to this subject since Allingham published his excellent monograph.[1]

The book and the principles it contains deserve careful study, for if experience demonstrates the correctness of its author's statements he will have contributed much to the successful treatment of the lesions he describes.

Musser's Diagnosis. A Practical Treatise on Medical Diagnosis. For the Use of Students and Practitioners. By JOHN H. MUSSER, M.D., Professor of Clinical Medicine, University of Pennsylvania. New (fourth) edition, thoroughly revised. In one octavo volume of 1,104 pages, with 250 engravings and 49 full-page colored plates. Philadelphia and New York: Lea Brothers & Co. 1900.

The previous, the third, edition of "Musser's Medical Diagnosis," issued only a year ago, has been exhausted and is followed by a fourth edition. It is only five years since the appearance of the first edition. This is a very positive evidence of the popularity of the work, a popularity which a critical acquaintance with its pages shows to be well deserved and creditable to the appreciation of those who use it.

The publication of frequent new editions at short intervals puts an author in a position to bring and to keep his book quite up to date, an important matter in these days of frequent changes, of new discoveries, of varying laboratory processes; and of this opportunity Dr. Musser has carefully and conscientiously availed himself.

[1] The Treatment of Internal Derangements of the Knee Joint by Operation. By Herbert Wm. Allingham, F.R.C.S. London: J. W. A. Churchill. 1899.

REPORT OF THE MEDICAL DEPARTMENT IN THE PHILIPPINES.

WE have before us a copy of the report of the chief surgeon of the Division of the Philippines, Dr. Charles R. Greenleaf, covering the first seven months of 1900. This report is included in General MacArthur's annual report on his military department for the year 1900 and is a document of unusual interest, both from the actual facts contained regarding medical conditions in the army of occupation, and also as indicating the deficiency of the present system and the needs of the future. The military situation has changed during the period covered by the report more than at any period of equal length since the beginning of the American occupation, due to the garrisoning of various posts at widely separated points throughout the islands. During seven months the number of these posts had increased from 123 to 375, leading to extraordinary demands upon the medical force, which has, in fact, been wholly insufficient.

The general health of the army has shown a gratifying improvement. The ratio of non-effectives to the whole strength until January, 1900, ranged from 9% to about 13%. The average for the succeeding seven months was 8.84%, although the period covered included those months which are most productive of sickness. Intestinal diseases, including typhoid fever, caused 35.2% of the total disabilities; malarial fever 23.2%; wounds and venereal disease furnished about an equal number, with a ratio of approximately 9% to 10% of the total. It is furthermore estimated that about 45% of the non-effective force suffers from disease which might be prevented were sanitation more perfected than is at present possible. It must also be borne in mind, the report insists, that sickness in the tropics is of much more serious moment than in temperate regions, because of the effect of the climate in retarding recuperation. The result of illness is therefore cumulative, each new attack of disease, perhaps not dangerous in itself, adding to the total, until permanent disability ensues. Malaria offers the best out-

look for recovery of the common diseases, but reinfection is common, and the general health is not infrequently permanently undermined. Tuberculosis, dysentery, typhoid and rheumatism are all serious in their final results. Venereal disease has been kept well within control, and adds but a small proportion to the total sick. Smallpox, through extensive vaccination, has also not proved a serious menace to life, although the disease has appeared in various localities.

Although disabling sickness has, on the whole, decreased somewhat, the number of deaths in the army has steadily increased. Dr. Greenleaf thinks that "by careful sanitary inspection, the sick list may be decreased by cutting down the number of preventable diseases, and this is hoped for and expected, but the non-preventable diseases will constantly become more severe in type and more intractable, owing to the increasing debility incident upon long continued tropical service." There has been an average death rate of 4.7 daily, with the ratio of deaths due to disease as compared with those due to wounds about 3 to 1. The mortality rate is about 26.7 per 1,000 a year, or 2.22 per 1,000 a month. Next to gunshot wounds dysentery has been the most fatal disease, much more so than typhoid fever. The prevention of the latter disease has been most creditable to the medical service, for the difficulties to be overcome in sanitation have been numerous and discouraging. Although the disease has a perfectly definite foothold in the islands there has been no extended epidemic among the troops. This admirable result has been brought about by strict care in isolation, disinfection, segregation of suspects, and vigilance in watching the non-infected portion of the command involved.

The all-important matter of sanitation is discussed at considerable length and contains many excellent suggestions, which it is to be hoped may be carried into effect. It is urged that a corps of duly authorized inspectors be organized. Heretofore it has been necessary to utilize such officers as have been available, who have naturally been somewhat inexperienced in the line of work they have been called upon to perform. The results have been good, but are not as gratifying as might be desired. The cessation of active campaigning, with its accompanying dangers, has been attended with certain distinct disadvantages. The monotony of garrison life, with the constant apprehension occasioned by the possibility of night attacks, has had a demoralizing effect upon the troops. More important has been the failure of officers and men to appreciate the sanitary difference between a stationary and a moving command. In the latter case the disposal of waste becomes a matter of paramount importance, a fact which even duly qualified medical men are slow in appreciating until they have had actual experience. Recognizing this, every effort has been made by the Medical Department to systematize sanitary inspection and to correct errors where found. The really serious difficulty in the way of carrying out this plan has been the wholly inadequate number of available medical officers. It is estimated that about 120 stations were (July 1st) unsupplied with medical men, a state of affairs clearly detrimental to the proper execution of sanitary laws.

As stated above, the extensive vaccination of natives has led to a most satisfactory result as regards smallpox. The disease has also been very slightly prevalent among the troops, constituting only .089% of the total mortality. Leprosy is a disease against which active measures are demanded. There is a large number of lepers scattered through the archipelago, probably about 30,000; for these an isolation island is needed, similar to the now famous Molokai of the Hawaiian Islands, if the progress of the disease is to be checked. Our impression is that since the printing of this report, definite action in this matter has been taken.

Considering the short time during which organization has been possible the hospital system appears to be in a fairly satisfactory condition. A well equipped pathological laboratory for the benefit of the hospitals in Manila, under the charge of R. P. Strong, Assistant Surgeon, U.S.A., is likely to prove of great value, and is doing much toward establishing all medical work on a higher plane of efficiency. Although no dogmatic statements are made Dr. Greenleaf seems to be of the opinion that soldiers invalided home are not likely to be again serviceable in the Philippines, owing to the strong tendency to relapse. Evidently more experience is needed, however, before any definite rule may be laid down.

Of the medical personnel the report speaks feelingly. There is a crying need of more physicians, and the need is growing greater continually because of the constant occupation of new posts. On August 10th there were 229 men to supply over 400 posts. When the report was submitted it was estimated that 500 medical officers were needed to properly care for the troops then in the Philippines. Dr. Greenleaf does not believe in the contract system, of which he says in part: "I am now more than ever impressed with the fundamental weakness of the contract system. To place civilians without real rank or authority in the position of quasi officers is an injustice to the surgeon himself, and to the Medical Department, which has to be responsible for his acts; his contract is made for one year only, and after that time he can demand his release from duty, no matter how urgently his services may be needed; while performing an officer's duties he is not one, and this knowledge makes him less exact and prompt in bending to military discipline; if he is wounded, he gets no pension; if he deserts and leaves his post unsupplied with medical attendance, there is no law known to me by which he can be punished or brought back and made to perform his duties; he gets a year's experience and is just beginning to know his duties when his contract expires, and an untrained man takes his place, and the process begins anew. Supplies are wasted, military papers are not properly made out, and to disci-

pline and train men for such short service is a hopeless task. The contract surgeon system is the least economical, the least effective and the least satisfactory system that could be devised." This is a severe arraignment, and one which should certainly have weight, coming as it does from a man who has had ample experience in the working of the system.

The report contains many facts not alluded to here, which are of great interest and importance. Its recommendations are reasonable and most temperately stated, and should receive the attention they deserve at the hands of those in authority.

MOSQUITOES AND YELLOW FEVER.

IF recent investigations are to be trusted, and there seems to be no reason to doubt their accuracy, the rôle of the mosquito as a conveyer of infection is about to be very materially extended. As is generally known, researches have been carried on for some months in Cuba by an army board consisting of Drs. Reed, Carroll and Agramonte, for the purpose of determining the relation of the mosquito to the propagation of yellow fever. These experiments have been carefully carried out, with the general result that a definite relation has been shown to exist between the insects and the fever. The establishment of this relationship has led the authorities of Havana to institute a systematic attempt to exterminate the mosquitoes by destroying the larval forms, as recently stated in another column. This is a "large contract."

In view of this investigation, which seems likely to have immediate practical results, it is of interest to call attention to a paper by Dr. Charles Finlay, of Havana, which has recently appeared in the New York *Medical Record*. Dr. Finlay has long been interested in the mosquito theory of yellow fever, and has from time to time written papers on the subject of much theoretic value, although they did not bring the conclusive proof which is demanded of a scientific theory. In 1891 Finlay concluded that the propagation of the disease might best be explained through the agency of an intermediate host, a condition which the tropical mosquito seemed to satisfy. Regarding this he says in his recent article to which reference has been made:

> The climatic and topographical conditions which are known to favor the propagation of yellow fever may be reduced to three: temperature (70° to 90° F.), atmospheric moisture with proximity to the sea or to water courses, and low levels (never exceeding 4,000 feet nor generally above a few hundred). The same conditions seem to be likewise indispensable for the vitality, functional activity, and reproduction of the "*Culex* mosquito." Being a hibernating insect whose functional activity can adapt itself only to tropical climates, it becomes benumbed and unable to sting when the temperature falls below 60° or 65° F., and it may thus remain in a condition of apparent death, from which, however, it will revive when the temperature is again raised to about 65° or 70° F., provided the refrigeration has not been carried to below the freezing point. Moreover, the same limits, below 65° or 70° F., appear to impede the transformation of the larvæ into the winged insect. On the other hand, temperatures beyond 95° F. also deprive the *Culex* mosquito of its movements, and it dies at 105° or 110° F. When the insect is confined in an atmosphere artificially rarefied to correspond to altitudes of 4,000 to 6,000 feet, it is unable to fly, at least for a while, or to sting. If we consider the smallness of its wings it seems unlikely that the *Culex* mosquito will, of its own accord, fly to any considerable height or distance, especially when weighted by the blood which it has ingurgitated. These peculiarities agree with what is known about the propagation of yellow fever, its tendency to invade the lower stories of buildings in preference to the upper ones, and its non-transmissibility in places like the City of Mexico, Puebla, Petropolis, situated at considerable altitudes above the sea level.

Finlay explains in a readable way how under the hypothesis of transmission by mosquitoes, certain outbreaks of yellow fever, otherwise difficult of interpretation, may be satisfactorily accounted for. It has, however, remained for the recent government commission to place the whole matter on a firmer experimental basis, so that from this time forth, no doubt, a systematic attempt will be made to exterminate the insects in those regions in which the disease is more or less endemic. It is hardly necessary to say that a much more complete investigation is required before the mosquito is made wholly responsible for the spread of the fever; it is altogether unlikely that there are not other modes of dissemination, a fact which we should not lose sight of in the enthusiasm of these new and far-reaching discoveries.

THE BRITISH CONGRESS ON TUBERCULOSIS.

THE last General Congress on Tuberculosis was held in Berlin; the next will be held in London, the King of England being president. The last congress was a most interesting and profitable occasion and the next promises to be no less so. The subject is eminently one of international interest, needing international study and co-operation. The main object of the forthcoming congress, as of its immediate predecessors, is to exchange information and experience gained throughout the world as to methods available for stamping out this, the most universal and destructive of all diseases. Papers will be read, and clinical and pathological demonstrations will be given, while the museum, a special feature of this congress, will contain pathological and bacteriological collections, charts, models and other exhibits. Leading authorities in all countries will be invited to contribute to the elucidation of the historical, geographical and statistical aspects of the subject. As a practical result resolutions will be formulated, it is hoped, calculated to indicate the public and private measures best adapted for the suppression of this widespread plague.

It is proposed to divide the congress into four sections: I. State and Municipal; II. Medical, including Climatology and Sanatoria; III. Pathological, in-

cluding Bacteriology; IV. Veterinary — Tuberculosis in Animals.

The meeting will open July 22d, and last through Friday, July 26th. The congress will consist of honorary members, delegates and members. Further information may be had of the secretary general, 20 Hanover Square, London, and to him abstracts of papers or communications should be sent on or before June 15th next.

MEDICAL NOTES.

THE PAST CENTURY IN MEDICINE. — The New York *Sun* has been publishing a series of notable articles on the progress of the last century in great subjects. The sixth paper in this series, on "Medicine," by Dr. Osler, of Johns Hopkins University, is a most satisfactory review. It is at once so simple and clear in language and form as to be perfectly comprehensible to the laity, and yet so free from the inaccuracies of half statements as to be perfectly acceptable to the initiated. This is no small praise. We must content ourselves with one extract from the opening paragraphs of an article which occupies twelve closely printed columns: "To us in the medical profession, who deal with this unit, and measure progress by the greatest happiness to the greatest number, to us whose work is with the sick and suffering, the great boon of this wonderful century, with which no other can be compared, is the fact that the leaves of the tree of Science have been for the healing of the nations. Measure as we may the progress of the world — materially, in the advantages of steam, electricity and other mechanical appliances; sociologically, in the great improvement in the conditions of life; intellectually, in the diffusion of education; morally, in a possibly higher standard of ethics, there is no one measure which can compare with the decrease of physical suffering in man, woman and child, when stricken by disease or accident. This is the one fact of supreme personal import to every one of us. This is the Promethean gift of the century to m n."

SANITARY CONDITIONS IN HAVANA. — The following statistics, provided by W. C. Gorgas, chief sanitary officer of Havana, show the general improvement in sanitary conditions in that city: "The number of deaths in December, 1900, was 485. The smallest number for any December in the preceding ten years was in 1893, with 517 deaths. We make an equally good showing when we come to compare the death rate 23.28 for 1900, the next smallest being that of 1899, when we had 27.10. The two smallest rates for December since 1890 have been those of the American occupation, 1899 and 1900. The rate for 1900, compared with that of 1899, for December, shows a continuous improvement over the conditions then existing. Last month we had 214 cases of yellow fever, with 54 deaths; this month 62 cases, with 20 deaths. This is a slight improvement over December of last year, when there were 70 cases, with 22 deaths. The little yellow fever we have comes almost entirely from the recently arrived Spanish immigrants, more than two-thirds of the cases having been here less than one year. Immigration still continues large, 4,206 for December."

ST. LOUIS CITY HOSPITAL ALUMNI. — At the annual meeting of the Medical Society of the St. Louis City Hospital Alumni, held December 20, 1900, the following officers were elected for the ensuing year: President, Dr. Norvelle Wallace Sharpe; Vice President, Dr. Francis L. Reder; Secretary, Dr. John Green, Jr.; Treasurer, Dr. Horace W. Soper.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, January 30, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 122, scarlatina 33, measles 59, typhoid fever 5.

REPORT OF WALTHAM, MASS., HOSPITAL. — The thirteenth annual report of the Waltham Hospital shows the number of patients admitted during the year to have been 586; the largest number of patients in the hospital any one day was 49; number of accidents received during the year was 30; number of bacteriological examinations for diphtheria bacilli was 1,903, and for tubercle bacilli 53; number of scarlet fever cases 42; diphtheria 171; deaths from diphtheria 7; deaths from all causes 34. There was an increase of 46.5% over the previous year in the number of in-patients treated.

BEQUESTS TO HOSPITALS. — By the will of the late Robert Codman, of Boston, the following bequests to hospitals are made: Five thousand dollars to the Massachusetts General Hospital; $5,000 to the Massachusetts Homeopathic Hospital; $5,000 to the Carney Hospital; $5,000 to the Boston Lying-in Hospital: $5,000 to the House of the Good Samaritan; $5,000 to St. Luke's Home for Convalescents, Roxbury; $5,000 to the Holy Ghost Hospital for Incurables, Cambridge.

STATISTICS OF MASSACHUSETTS HOSPITAL FOR DIPSOMANIACS AND INEBRIATES. — According to the superintendent's report of this hospital it is learned that the past year has been the most active in the history of the hospital; beginning with 174 patients, it closed with 258 — an increase of 84. The number of commitments was 418 — a gain of 108 over the preceding year.

MEETING OF MASSACHUSETTS ASSOCIATION OF BOARDS OF HEALTH. — At the annual meeting of this association, held recently in Boston, there was a discussion on the topic of "Glander in the Human Subject." A paper was also presented by William Lyman Underwood, on "Drainage of Wet, Rotten and Spongy Lands in Cambridge and Belmont."

A POSSIBLE HOSPITAL FOR CONTAGIOUS DISEASE AT CAMBRIDGE, MASS. — The Board of Health of Cambridge is discussing the advisability of the estab-

lishment in the city of a hospital for the treatment of contagious disease. Mayor Dickinson is said to favor the plan.

A CENTENARIAN. — Mrs. Anna Graffam, of Lewiston, Me., died January 23d, at the reputed age of one hundred and one years and nine months.

DIPHTHERIA IN CAMBRIDGE, MASS. — Several new cases of diphtheria have been reported to the Board of Health in Cambridge.

NEW YORK.

REFUSAL OF MUTUAL LIFE INSURANCE CO. TO PAY POLICY. — The refusal of the Mutual Life Insurance Company, of New York, to pay the $240,000 policy of the late James C. Pearson, of Boston, has developed a legal question said to be unique in insurance annals. The refusal is based on the ground that Mr. Pearson, who four days previously had passed a successful physical examination, was operated on for appendicitis the very day the policy was taken out and the first premium paid. Death occurred within twenty-four hours after the operation. The company in taking this action relies upon the following clause in its application contract: "And this contract shall not take effect until the first premium shall have been paid during my continuance in good health." It has announced its readiness to return to the heirs the $15,000 constituting the first premium on the policy. Heirs of Mr. Pearson on January 25th filed claim for the full amount of the latter, and their claim raises the interesting question of an insurance company's liability on a policy for which the taker had been accepted by the company's medical examiners, but which was taken out at a later time, when the prospective holder was lying dangerously ill. The family assert that Mr. Pearson's private secretary, who attended to the taking out of the policy after his employer's return to Boston, from New York, acted in entire good faith, being unaware of the latter's sudden and serious illness.

A CASE OF SMALLPOX AT BELLEVUE. — The first case of smallpox met with in Bellevue Hospital since the beginning of the outbreak in the city occurred during the past week. The patient, a young man of twenty, who was admitted one evening about 5 o'clock, remained in the wards over night. He was supposed to be suffering from influenza and it was not until the following day that the true nature of the disease was discovered.

EXTENSION IN USE OF WIDAL REACTION. — Dr. Doty, health officer of the port, has had sent to physicians throughout the State, outside of the larger cities having facilities for bacteriological work, circulars explaining the availability of the Widal reaction in the diagnosis of typhoid fever and offering to test at the quarantine laboratories specimens of blood or serum forwarded by any physician in the State.

TUBERCULOSIS AND TYPHOID AT SING SING. — Dr. Daniel Lewis, president of the State Board of Health, has made a report on the State prison at Sing Sing in which he calls attention to the prevalence of phthisis and typhoid fever there, and condemns the buildings as unfit for their purpose on account of their low situation and the bad sanitary condition of the premises.

Miscellany.

APPETITES AND PASSIONS.

THE *Lancet* has recently commented, in part, as follows on two pamphlets, entitled respectively:

"'Counsel for Young and Unmarried Men Respecting Chastity,' and 'The Proper Discipline to be Observed by Married People in regard to Conjugal Intercourse,' and they are stated to be issued 'on high medical authority and with episcopal sanction.' Their object is sufficiently indicated by their titles. The medical authority concerned in the production dwells with suitable brevity upon the physiological aspects of the case and his observations are accurate and to the point. If we cannot speak as highly of the advice emanating from the 'clerical' authority this is not because we do not see that a sincere attempt has been made to do good. We have two or three general observations to submit on the subject, and more than general observations we cannot make, for individual appetites so vary that we do not wish to be the medium for recording any hard-and-fast limits, even while we see the benefit that might accrue to some people from such guidance. In the unmarried, and especially in the young, continence is the noble aim. We do not dwell for the moment (though this aspect is vitally important) upon the narrower and more selfish view of the physical and moral evils which incontinence may produce; we rather assume the higher ground that a man who ruins, or helps to maintain the ruin of, a female is a sinner against the social law of love. Each young man should act as a trustee for the chastity of every woman and should account as a personal insult and degradation any suggestion to mar her highest development into the type of womanhood. This is the ideal attitude towards unchastity, whether it be assumed out of physiological knowledge, out of faith in the beneficent effect of a Divine will, or (best of all) out of a fortunate blend of both reasons. But incontinence besets the married as well as those to whom sexual gratification is morally forbidden. In married life, as members of our profession know only too well, there frequently occurs a reversion to primitive customs. The wife is still too often considered to be largely a mode of sensual gratification to the man instead of a helpmate, entitled to equal respect of her feelings and sense of dignity. This is well known to the medical man, for it is part of the routine of his life to receive confidences of a perfectly intimate character. And his counsel, based upon knowledge that no general laws can be laid down, is always towards moderation. But we would suggest to the Church a reform of the marriage service, which in its present terms encourages the belief that marriage is largely a device for the multiplication of children, and that the wife in this respect is to 'obey' the demands of a husband, however insatiable. Any teaching which appears to support this view can only debase,

rather than elevate, married life. The Law, following in the steps of the Church, gives a carnal interpretation of marriage, and treats the tie as mainly one of sensual meaning, and so the full dignity of conjugal union is missed. We need an equitable and righteous reform, possible only under fresher and purer conceptions, and a more elevated view accordingly of the married state — a state in which the intellectual, moral, social and spiritual affinities between man and wife shall be cultivated and sought, in place of the more debasing notion which is too generally sanctioned by Church and Law, and which largely forms the predominating element in popular views. The Law by the growing recognition of the personal rights of the wife has shown that its purview of married life is becoming larger and more liberal. Medicine plays its part by inculcating moderation. There are ways in which the Church might help."

Correspondence.

AN ACADEMY OF MEDICINE.

BROOKLINE, January 25, 1901.

MR. EDITOR: The dedication of the new Boston Medical Library building and the recent anniversary of an old medical society lead me to ask the question if it is not possible that the medical profession may be entering upon a new era of activity and progress. While it can be said with truth that scientific medicine has made extraordinary strides in the last fifty years, it appears to me that during this "period of ether" in some ways our social instincts in Boston have been lulled into a condition of somnolence. We have kept our ideas and feelings in cold storage, making such contributions to science out of this store as circumstances demanded, and then rested satisfied with the slight rise of temperature ensuing.

Our growth on the human side, however, has been less, and while perhaps the mutual relation between the physician and patient is as close and intimate as treatment renders absolutely necessary, something of the old-time sympathy and friendliness has become less apparent. With the profession divided into many specialties, general intercourse among physicians also has assumed a different character and there is less co-operation among us. To some extent this may be inevitably necessary, but I believe not to such a degree as is at present the case. We have developed the scientific at the cost of the more human side of our work. If this state of things is to be overcome, and I believe there is a reaction in this direction, we must fan the flame of social intercourse to bring the members of the profession, old and young, together, and make them to each other something more than men of stone and iron. Before the new Medical Library building was finished, it was less easy to do this, as many will bear witness who attended meetings in the old building. It was a good deal like descending into a tomb to go into the old hall and the general atmosphere struck the chill of the grave into one's bones, affecting the men and even the character of the papers they read, which were often corpse-like enough to suit the surroundings.

In the new building all is different; everything is bright, cheerful and suggestive of hope. It is a place where all medical men may meet together, not as icicles, but as brothers of one profession. As, however, there are many of them who have little acquaintance with one another, it is important that there should be distinctly social occasions where men may have a chance to eat something, and smoke and have a practical realization that even the most exalted men of our profession are not too good for human nature's daily food and not even above small beer and cheap cigars. Above all, let us not become pedants and scientific machines unable to give utterance to anything that will not stand the test of laboratory analysis.

I hail the suggestion of an academy of medicine with delight, as I believe that it can accomplish the purpose on the one hand of improving the general standard of scientific excellence of those who lag behind, and on the other, of bringing to the surface and making potent those social feelings and instincts which have been too prone to lie dormant in another large part of our profession.

I hope that no old society will be rehabilitated, but rather that the academy will be a new movement free from old prejudices and representative of all that is best morally, socially and scientifically. It should contain all of those men who by high aims and serious work show themselves to be worthy members of the profession. To belong to it should not only be an honor but a joy as well, which cannot be said of membership in some of our societies.

One useful purpose the academy can serve is to assume some of the financial burdens of the Medical Library, which must be considerable if it is to go on developing. I believe if properly organized it could raise a large fund, and I hope this side of the matter will receive due consideration in its formation. Let an endowment fund of not less than $50,000 be guaranteed at the start. If subscribers can be allowed a period of time like five years to complete their subscriptions, it will be more possible to obtain such an amount.

Very truly yours,
WALTER CHANNING, M.D.

KIRKES' HANDBOOK OF PHYSIOLOGY.

CAMBRIDGE, MASS., January 27, 1901.

MR. EDITOR. — I have noted Dr. Harris's letter, "*Re* 'Kirkes' Handbook of Physiology' in America," in last week's number of the *Boston Medical and Surgical Journal*. Dr. Harris could not have read the reviews carefully or he would understand "that the gloomy forebodings of your reviews" — when the statement was ventured that "probably in a few years this publication will be a thing of the past" — did not apply to "Kirkes' Physiology" as produced by Professor Halliburton, but to the "Baker and Harris" edition produced in this country. It has already been pointed out that this edition (Baker and Harris) is already a "thing of the past" in England. May the good work continue!

Yours faithfully,
ALLEN CLEGHORN, M.D.

[We can give no more space to this subject. — ED.]

METEOROLOGICAL RECORD

For the week ending January 19th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Melrose	12,962	5	1	20.00	—	—	—	20.00

Deaths reported 3,204; under five years of age 787; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 643, acute lung diseases 612, consumption 337, diphtheria and croup 129, diarrheal diseases 39, typhoid fever 39, scarlet fever 31, whooping cough 8, measles 6, cerebrospinal mengitis 5.

From whooping cough Philadelphia 2, New York, Pittsburg, Boston, Worcester, Malden and Newburyport 1 each. From cerebrospinal meningitis Baltimore, Pittsburg, Worcester, New Bedford and Everett 1 each. From scarlet fever New York 22, Boston 3, Philadelphia and Pittsburg 2 each, Baltimore and Salem 1 each. From measles New York 3, Boston 2, Pittsburg 1. From typhoid fever Philadelphia 12, New York 11, Baltimore and Pittsburg 5 each, Providence 2, Boston, Worcester, Lynn and North Adams 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,789,099, for the week ending January 5th, the death rate was 17.5. Deaths reported 3,964: acute diseases of the respiratory organs (London) 330, diphtheria 79, whooping cough 71, measles 56, fever 47, diarrhea 37, scarlet fever 33.

The death rates ranged from 8.7 in Derby to 22.5 in Liverpool: Birmingham 17.4, Bradford 17.2, Bristol 14.6, Cardiff 13.9, Gateshead 18.6, Halifax 18.1, Hull 15.9, Leeds 20.3, London 17.9, Manchester 21.5, Newcastle-on-Tyne 15.2, Norwich 11.2, Nottingham 15.3, Plymouth 17.6, Portsmouth 12.0, Salford 20.1, Sheffield 21.4, Sunderland 17.1, Swansea 16.5, West Ham 15.4.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 26, 1901.

C. N. FISKE, assistant surgeon, detached from the "Wheeling" and ordered to the "Mohican" when the former is put out of commission.

H. O. SHIFFERT, assistant surgeon, appointed assistant surgeon from December 26, 1900.

D. N. BERTOLETTE, medical inspector, detached from the Medical Examining Board, Washington, and ordered home January 31st.

A. C. H. RUSSELL, surgeon, ordered to Washington, for duty as a member of the Medical Examining Board, January 31st.

W. H. RUSH, surgeon, ordered to the Pensacola Naval Station for recruiting and other duty.

R. K. SMITH, passed assistant surgeon, detached from the "Pensacola," February 2d, and ordered to the "Wisconsin," February 4th.

M. V. STONE, assistant surgeon, detached from the "Solace" and ordered to the "Isla de Luzon."

H. H. HASS, assistant surgeon, detached from the "Isla de Luzon" and ordered to the "Solace."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING JANUARY 24, 1901.

PURVIANCE, GEORGE, surgeon. Granted leave of absence for two days. January 18, 1901.

WILLIAMS, L. L., surgeon. Granted leave of absence for three days. January 21, 1901.

BEAN, L. C., acting assistant surgeon. Granted leave of absence for two days from January 18th. January 17, 1901.

CRAIG, R. C., acting assistant surgeon. Granted seven days' extension of leave of absence. January 22, 1901.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—The regular meeting of the society will be held in Sprague Hall at the Medical Library Building, 8 The Fenway, on Monday, February 4th, at 8.15 P. M.

Papers: Dr. Henry Jackson, "Disease of the Myocardium."

Dr. Horace D. Arnold, "The Condition of the Myocardium as Affecting Cardiac Murmurs."

ARTHUR K. STONE, M.D., *Secretary*, 637 Boylston Street.

SUFFOLK DISTRICT MEDICAL SOCIETY, SURGICAL SECTION.—The Surgical Section will meet at the Medical Library, 8 The Fenway, on Wednesday evening, February 6, 1901, at 8.15 o'clock.

Papers: "Relief Afforded by Operation on Abdominal Adhesions," by Dr. A. T. Cabot.

"Report of Cases of Sarcoma," by Drs. Munro, Blake and Lund.

F. G. BALCH, M.D., *Secretary*, 279 Clarendon Street.

RECENT DEATHS.

AUGUSTINE SHURTLEFF, M.D., M.M.S.S., died in Brookline, January 27, 1901, aged seventy-four years.

CHARLES WISTAR STEVENS, M.D., M.M.S.S., died in Charlestown, January 25, 1901, aged sixty-four years.

ERSKINE E. HAMILTON, M.D., died in Springfield, Mass., January 24th, at the age of thirty-four. He was graduated from the College of Physicians and Surgeons, New York.

HENRY J. HERRICK, M.D., a well known physician of Cleveland, O., died January 28th. He was for many years a professor in the Medical Department of the Western Reserve University

JAMES WATSON STRONACH, M.D., of New York, died in Belleville, N. J., on January 23d, of cardiac disease, aggravated by influenza. He was born in Forres, Scotland, in 1834, and was graduated from the Medical Department of the University of the City of New York in 1872.

BOOKS AND PAMPHLETS RECEIVED.

Report of the Laboratory of Pathology of the University of Buffalo, Medical Department. No. 1. 1900.

Report of the Surgeon-General of the Army to the Secretary of War for the Fiscal Year ended June 30, 1900. Washington. 1900.

Uterine Tumors: Their Pathology and Treatment. By W. Roger Williams, Fellow of the Royal College of Surgeons. New York: William Wood & Co. 1901.

Introduction to the Study of Medicine. By G. H. Roger, Professor Extraordinary in the Faculty of Medicine of Paris, etc. Authorized translation by M. S. Gabriel, M.D. With additions by the author. New York: D. Appleton & Co. 1901.

Experimental Research into the Surgery of the Respiratory System. An essay awarded the Nicholas Senn Prize by the American Medical Association for 1898. By George W. Crile, A.M., M.D., Ph.D. Second edition. Philadelphia: J. B. Lippincott Co. 1900.

A System of Practical Therapeutics. Edited by Hobart Amory Hare, M.D. Second edition, revised and largely rewritten. Vol. I. General Therapeutic Considerations; Prescription Writing; Remedial Measures other than Drugs; Preventive Medicine; Diathetic Diseases and Diseases of Nutrition. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1901.

A Series of Original Papers on Gonorrhea.

GONORRHEAL INFECTION.[1]

BY BENJAMIN TENNEY, M.D., BOSTON.

IN the last few years intelligent opinion has settled on the gonococcus of Meisser as the bacterial agent in practically all cases of urethritis. The consideration of non-gonorrheal urethritis by Guiard, published in the French journal of genito-urinary diseases for 1897, leads him to a conclusion which I am sure we will all endorse, namely, that every case of urethritis which lasts more than a few days is, or at least may have been at the start, a true infection by the gonococcus. Certainly today no patient's story of "strain" or error of diet will be accepted as conclusive evidence of a non-gonorrheal urethritis, and no man familiar with laboratory methods will accept any sort of argument short of a most careful bacteriological examination.

That mild and transient inflammations of the urethra, with purulent discharge, do occur in the course of acute fevers, attacks of gout or articular rheumatism, and are acquired from instruments or from sexual contact must be admitted. I have seen 2 cases recently, with a slight mucopurulent discharge lasting three and four days, in which I was unable to find any organisms which decolorized by the Gram method. The pus cells contained large diplococci which resembled, both in size and in their growth on agar, diplococci which I have obtained from male urethræ which had never been infected by the gonococcus.

Guiard reports cases of typhoid fever, secondary syphilis, malaria, rheumatic fever and gout where satisfactory examinations were made and no gonococci found.

In no other reported cases, whether attributed to mumps, diabetes, tuberculosis, or articles of diet, does he consider the claim proved. In discussing non-gonorrheal urethritis due to sexual contact, he mentions 1 case where a man contracted a urethral inflammation, lasting a short time, showing no gonococci, from a woman who showed a few typical gonococci in leucocytes from her urethra and posterior cul-de-sac of her vagina. He quotes 30 cases described by Ranzier, Bockhardt, Legrain, and others where the urethritis lasted but a few days and showed no gonococci. In 1 case the bacillus coli communis was found, and in the others a variety of cocci, one of which after being isolated in pure culture produced a transient inflammation in several healthy urethræ. He personally has never seen an acute case where he felt sure the attack was not primarily due to the gonococcus, though the infecting material may not have contained the living germs but only some substance produced by their growth, which has the power of poisoning the urethral epithelium and destroying its resistance to less virulent germs.

As to the progress of gonorrheal infection on mucous membranes, I have found nothing of value in the literature since the work of Bumm published in 1885 and that of Legrain in 1888. They agree that the growth of the organism may be divided into three stages: (1) On and in the epithelial cells; (2) in the subepithelial layer and leucocytes, where they develop very rapidly; (3) in the epithelial cells again, as the growth of a sort of dam of new tissue beneath them furnishes a layer unfavorable to the development of the gonococci. This certainly agrees with the smears which we get in the different stages, and with the pathological description of a urethra which Bockhardt obtained ten days after inoculation with a pure culture. Bumm's work was done on the conjunctival mucous membrane of babies infected during delivery, and the specimens were from one and a half to thirty-two days after birth. After twelve hours the organisms were in the epithelial cells and a few leucocytes were appearing. From the third to the sixteenth day the gonococci were in the pus cells and subepithelial tissue, on the eighteenth day only in the superficial layer, on the twenty-third day a few in edges of the most superficial cells, on the twenty-fifth day only on surface and in detached epithelium, and on the thirty-second day he found no gonococci.

The persistence of the infection is a matter of great importance and also a matter where the greatest care in diagnosis is necessary. In the acute stage diplococci in the pus cells can be taken to represent gonococci with almost any bacterial stain, and the resulting error will be slight and not important. In the declining stage, when pus cells must be found on the threads or by sedimentation, the greatest accuracy in staining by Gram's method is essential. Many men are reasonable and the reasonable man will take no chances of infecting others so long as knows the probability of his doing so. Moreover, there is always the possibility of his reinfecting himself. The often quoted statement, "once infected, always infected," was made by the Noeggerath who spread abroad those remarkable statistics of New York men and women, and the statement is entitled to about as much consideration. While we know that this germ in some individuals will reproduce itself for months and even years, in some pocket of the urethra, prostate or seminal vesicle, it usually disappears within three to five months. It must always be remembered that the normal urethra which has never been infected by gonococci carries diplococci which very closely resemble the gonococci when stained with the ordinary methyl blue. I have never been sure of the difference under these conditions.

The persistence of the infection appears to be due to the same constitutional conditions which favor the infection. One of my patients in whom the undoubted gonococci could be found two years after his last infection, finally married with my consent and has a healthy wife and fine children, but has become a sufferer from periodic attacks of gout. Another, who came to me eighteen months after infection, had a slight consolidation in the apex of one lung, as well as a gleety discharge containing gonococci. Both disappeared after a few months in Colorado. Cases where the use of alcohol is persisted in are well known to run a long course, and the first instruction given to every gonorrheal patient in the clinics as well as in the office is "no rum."

But outside these three conditions which are well recognized as favoring its continuance, the usual result of careful treatment is a complete cure so far as the possibility of harm to the patient or his family goes.

Every practitioner knows of men who have had

[1] Read before the Boston Society for Medical Improvement, December 31, 1900.

gonorrhea at some time, and who have married and had healthy wives and clear-eyed children. If this were not the rule, I fear the proportion of pus tubes would be even greater than at present, both in private practice and clinics. That sterility may and often does result from a gonorrheal infection is a simple and reasonable proposition, but sterile marriages are not necessary sterile because the wife has been infected by the husband. He may have became incapable of impregnating by the obliteration of his seminal canals, and then have starved out his gonococci, before marriage. I cannot believe, nor do the gynecologists with whom I have talked believe, that infection of a wife by a husband who has had no visible discharge for months is at all a common event. Nevertheless it undoubtedly has occurred in some cases, and I regard it a part of the duty of the doctor who treats men with this disease to have a square talk with every patient, and fully explain why he ought to make sure by as competent an examination as he can get that he is completely free of his gonococci before he marries, no matter when that may be.

The most interesting recent work has been done on toxin production by the gonococcus. Christmas, in the *Annals of the Paris Pasteur Institute* of May last gives the latest results of his and others' work. He cultivated gonococci on a medium composed of three parts of human ascitic fluid with one part of rabbit bouillon. He produced a poison, .002 of a cubic centimetre of which, diluted with salt solution and injected into the brain of a guinea pig, kills the pig in five to seven hours, while the same bulk of salt solution without the poison produces hardly a symptom. The total bulk of the injection was always .05 cubic centimetre. Smaller doses produce death after a longer time, or else a form of intoxication from which the animal recovers with a certain acquired immunity to the poison. This immunity can be increased by successive doses until the serum of the animal's blood contains an antitoxin which can be used to neutralize the toxin injected into a fresh animal.

A year ago he had an antitoxic serum which neutralized two hundred and fifty times its bulk in fatal doses. This neutralization he accomplished by mixing the two at ordinary temperatures, three or four hours before injection, by injecting both toxin and serum into the brain at the same time, though not necessarily into the same hemisphere, or by injecting the serum within three days before the toxin. His antitoxin has no effect when injected after the toxin. He injected 2 cubic centimetres of a one-tenth dilution of this toxin into a human urethra and allowed it to remain two or three minutes. It produced a burning sensation and was followed by a mucopurulent discharge without gonococci lasting a few days. It remains to be seen whether this work has any practical value to the human animal. As the damage and discomfort to the ordinary individual appear to be due more to the marvellous fertility of the organism than to its toxin-producing power, one would think the usefulness of an antigonotoxin would be limited to the complications of gonorrhea which are accompanied by constitutional symptoms, but time will show.

Another matter of great interest in considering this infection is the proportion of the community which becomes infected at some period of life. For obvious reasons this becomes a mere matter of estimation, and the estimates vary greatly. Noeggerath is quoted as having claimed that in New York City 800 out of every 1,000 men suffer from this infection. Further, that 90% of these are married men, and that 3 out of every 5 married women have become infected. This is absurd on the face of it. Another Continental writer says that in the large cities 10% of the married men have chronic gonorrhea and another 10% acquire it after marriage. From this he computes in some way that 5% of all married women become infected.

Still another found 10% of 1,930 gynecological cases suffering from the effects of the disease, and in a later series of 161 cases 18% were found infected. This leaves a margin of 8% of those who were infected but not suffering. Let us suppose that 18% of all his hospital and private cases were infected, we have still to inquire what proportion of the women of his town were gynecological cases. If half of them could be classed as such, the total proportion of women infected would be 9%, which may be a fair estimate for a Continental city.

Another estimation comes from my own experience. In a country college class of 80, where I had rather exceptional opportunity for knowing the personal life of every man, I knew of 4 who contracted gonorrhea. If we double this to cover men whose condition I did not know, which would be very liberal, and then allow that as many more have contracted gonorrhea since their college days, we have a total of 16, or 20%. These men would be fairly representative of the native born population of our country — some from city families of large wealth, most from families of comfortable condition, and a few who were working to pay their own way through.

Men who are especially interested in this subject can hardly help overestimating the proportion of cases of gonorrhea, and even those who treat these cases from the standpoint of the surgeon or general practitioner are prone to forget the great mass of mankind who require the services of neither until the time comes to die decently and in order. My present impression is that 20% of the males and 5% of the females of the community may have become infected at some time, but certainly no more. I hope to have some more reliable statistics later, bearing on the proportion of males infected, but at present it is all a matter of approximation to the correct figures.

With most of the contagious diseases a period of immunity follows the attack, but with this disease the common impression is that the opposite is true. There is little in literature and nothing in the history of my own patients which bears exactly on this point. The only reference made to this is in some experimental work of Judassohn, who introduced pus from a fresh gonorrhea into six urethræ which were in the chronic stage. Of these two only started afresh.

Without question gonorrhea resembles other bacterial diseases in the resistance offered by different individuals to its progress and even to its onset. Some individuals lead promiscuous lives for years and escape infection, even having contact with immunity where others acquire gonorrhea. Some individuals acquire a gonorrhea, have no complications, and regard themselves cured of a disease no worse than a hard cold in four or five weeks. Others acquire a disease which in onset, incubation and bacterial diagnosis differs in no demonstrable way from the preceding type, and yet they carry a mucoid discharge or shreds in the urine, showing pus cells with gonococci,

for months. In most cases the gonococci probably are confined to the urethral tissues, while in others they escape by the blood or lymph channels to find lodgment in some joint or tendon sheath, or even in the heart. Chance is the lack of reason usually assigned to cover these conditions, but there is more than chance in it. It seems to me a reasonable proposition that the same conditions which favor the persistence of the disease, and stimulate the pathological process, should also favor the infection.

The chief conditions which we recognize as having this power are the use of even moderate amounts of alcohol, sexual excitement, a tendency to gout or rheumatism and tuberculosis. The use of alcohol has especially interested me. I have never had a gonorrheal patient who was a total abstainer and rarely one who did not admit an excess of alcohol at the time of his infection. This, of course, can be reasoned out in two ways. Without an excess of alcohol a man's moral sense, or his prudence, would keep him from exposing himself as he does when he has the excess. But I cannot help believing that alcohol in the circulation or in the urine affects the urethral epithelium and partially destroys the normal resisting power of the cells. How else can we explain the fresh start which a declining gonorrhea takes when the patient fails to follow our advice to "let rum alone"?

In the July number of the *Journal of Experimental Medicine* for 1896, Abbott reports the results of his work on the influence of acute alcoholism on the normal vital resistance of rabbits to infection. He administered alcohol before and after inoculating the animals with pure cultures of human bacteria, using the bacillus coli communis, the streptococcus and the staphylococcus aureus. Throughout his experiments "the alcoholized animals not only showed the effects of inoculation earlier than did the non-alcoholized rabbits, but in the case of the streptococcus inoculations the lesions produced were much more pronounced than are those that usually follow inoculation with this organism." Some preliminary work of my own on the infection of rabbit urethra with gonorrheal pus has been very significant in its results, though as yet not conclusive. But if by administering alcohol in doses sufficient only to produce a mild intoxication we can diminish animal resistance to human infections, it is certainly not a wild deduction that the same process occurs in man. I would not maintain that alcohol is the only reason for the usual human susceptibility to this organism, but I do believe that it has an influence which is too little recognized at present.

THE BACTERIOLOGICAL DIAGNOSIS OF THE GONOCOCCUS.[1]

BY OSCAR RICHARDSON, M.D., BOSTON,
From the Clinico-Pathological Laboratory of the Massachusetts General Hospital.

THE following paper presents the views held in the Laboratory of the Massachusetts General Hospital in regard to the bacteriological diagnosis of the gonococcus.

Owing to the absence of Dr. James H. Wright, the director of the laboratory, it has devolved upon me to state what those views are.

[1] Read before the Boston Society for Medical Improvement, December 31, 1900.

For practical purposes the gonococcus may be identified with a reasonable degree of certainty in suspected gonorrheal pus by cover-glass examination. This method of identification depends upon the fact that the gonococcus differs from the ordinary pus cocci in being decolorized by Gram's method of staining. Its morphology and its position inside the leucocytes are by no means diagnostic, for other cocci may be found inside leucocytes which are indistinguishable from the gonococcus in shape. The important diagnostic point, therefore, for the gonococcus is its property of decolorizing by Gram's method. The other points, of morphology and position inside the leucocytes, are not necessarily characteristic. It has been claimed that in gonorrheal pus cocci may be found which decolorize by Gram's method, and which are not gonococci, but we have never seen such microorganisms.

The application of the method of cover-glass examination combined with Gram's method of staining for the identification of the gonococcus is a simple manipulation, and the details of the method need not be repeated here, but it requires some experience on the part of the person doing it, or it may lead to erroneous observations. The method must be applied with certain precautions which, as a rule, are apt to be neglected. Practically the most important precaution is to smear the pus properly on the cover glass. Usually it is too thick.

In general, it may be said that the best preparations are those obtained by scraping off the pus from the cover glass as much as possible with a platinum loop or knife point, after it has been placed thereon. This procedure spreads out the leucocytes in a thin film, allows the reagents to act well and gives a clear and definite picture under the microscope.

Another important precaution to be observed is to be sure that the aniline oil gentian-violet solution has not decomposed. This solution should not be used when it consists simply of a clear fluid and a brown sediment. To avoid errors in this regard, the solution should not be more than two weeks old.

So far we have only considered the recognition of the gonococcus in gonorrheal discharges from the standpoint of the practical man. From the so-called scientific standpoint, we cannot consider the cover-glass examination as being conclusive. The results of the cover-glass examination from this point of view must be controlled by cultures and it is necessary to isolate the suspected coccus and further prove its identity by the determination of its cultural peculiarities.

The use of cultures for the determination of the gonococcus may be considered also to have a certain value over the cover-glass examination alone, because it might enable us to determine the presence of the gonococcus when it is present in very small numbers. Culture methods have been applied to the solution of the question of the infectious nature of gonorrheal shreds with more or less success. We have had no practical experience with this subject, but we think that we are safe in saying that a negative result with cultures from gonorrheal shreds by no means excludes the presence of gonococci in them.

From the standpoint of the pathologist, the chief interest today attached to the gonococcus is the rôle it plays in inflammatory processes, other than in gonorrhea. The identification of the gonococcus in pyo-

salpinx, arthritis, tenosynovitis, endocarditis, and in peritonitis requires more than the simple cover-glass examination and the application of Gram's method of staining. In these conditions the pathologist demands that the suspected organism be isolated in pure culture and its peculiarities in cultures shown to agree with the well-known peculiarities of the gonococcus. If cultures are not applied, the results of cover-glass examinations, although agreeing with the idea that the gonococcus is present, amounts from a scientific standpoint to little more than a probability. In other words, it does not suffice to prove that a given case of arthritis is due to infection with the gonococcus by showing that Gram decolorizing cocci inside of pus cells are present in the exudate, but it must be shown in addition to this that these cocci will grow only on special culture media and it must be rigidly determined that they will not grow on ordinary culture media.

Furthermore, it must be shown that these colonies on special culture media have certain appearances, and that the micrococci composing such colonies are decolorized by Gram's method and have a decided tendency to group in fours. The test of the behavior of the cocci, so isolated, towards the Gram staining reaction is of great importance, and is to be applied with certain precautions.

The first of these precautions to be observed is that the culture must not be more than forty-eight hours old, because some Gram staining cocci in older cultures will be observed to be decolorized when treated by Gram's method. The second is that the cover-glass preparation should not be made too thick, and the judgment, as to whether the coccus decolorizes or not after treatment with Gram's method, should be made only from portions of the field where the cocci are well separated from one another and not from portions where the cocci are aggregated in masses. This precaution is necessary because, where the cocci are aggregated in masses, those in the interior of the mass escape the action of the reagents. These criteria for the identification of the gonococcus in cultures must be rigidly carried out in order to avoid a very easy mistake in bacteriological diagnosis. In brief, no culture of a micrococcus is to be regarded as a culture of the gonococcus unless the organism grows only on special media in colonies of a certain appearance, decolorizes by Gram's method and shows a decided tendency to grouping in tetrads.

The necessity of rigidly subjecting the suspected gonococci, obtained in cultures, to these criteria has been emphasized by a recent observation of a case of acute arthritis of the knee clinically of gonorrheal origin. Cover-glass examination of the exudate showed Gram decolorizing cocci inside of the pus cells which were regarded at the time as gonococci. The cover-glass examination of the vaginal discharges also showed micrococci inside pus cells decolorizing by Gram. At the time the pathologist had no doubt but that the case was one of gonorrheal arthritis. The cultures, however, from the exudate in the knee showed an organism which had a considerable resemblance to the gonococcus, so much so, indeed, that it was only after it had been cultivated through a number of generations and had been carefully subjected to the foregoing criteria that the pathologist was compelled, against his will, to decide that the coccus was not the gonococcus. It was found to grow on ordinary culture media. Its colonies were not identical with those of the gonococcus, but sufficiently so to come within bacterial variations. It decolorized by Gram like the gonococcus, but it did not show the decided tendency, possessed by the gonococcus, to group itself in fours.

Concerning the relationship of this organism to the gonococcus, the pathologist has nothing to offer, except to say that he does not think that this organism should be regarded as a variety of the gonococcus.

In conclusion, a word might be said concerning the frequent negative results of the bacteriological examination of inflammatory conditions supposed to be due to the gonococcus. The common experience in cultures from pyosalpinx, arthritis and similar conditions is that no bacteria grow on cultures on special media, nor are any bacteria found by cover-glass examination. We are inclined to explain these results as being due to the destruction of the gonococci after their arrival in the tissues, rather than as being due to the results of a toxin transported there from a distance. It seems reasonable to suppose that the gonococcus might set up a very active inflammation and an accumulation of inflammatory products and then die out, leaving, however, these products as an irritating body to continue the inflammatory process.

Moreover, we know that the bodies of dead gonococci have irritating and pyogenetic properties. Certain it is that in many instances of arthritis and of pyosalpinx the most painstaking examination may fail to show any sign of the gonococcus or other bacteria.

TREATMENT OF ACUTE GONORRHEA.[1]

BY FRANKLIN G. BALCH, M.D., BOSTON.

THIS is not to be an elaborate article on acute gonorrhea, but rather a short paper telling of some of the methods from which I have seen results.

As to prevention. — Some people have told me that after a doubtful connection they always take an injection of a weak solution of permanganate of potash, and that they never become infected when they have done so. For a person who understands how to take an injection, and who can be relied upon not to try it when under the influence of liquor, this may be a safe procedure, but for the ordinary run of such people it is unwise and liable to be productive of more damage than good. I have had patients come to me the day after and have irrigated the urethra myself with permanganate, 1 to 4,000, or a 4% solution of boracic acid. In none of these cases has a gonorrhea followed, but I am very doubtful whether it would have anyhow. Theoretically it should be an extra safeguard, for the gonococci would not then have penetrated the cells and could easily be reached by an antiseptic.

If, however, a person has been infected and comes for treatment with the very first appearance of any moisture at the meatus, or perhaps only a slight tickling sensation, what advice should he receive? There are so many sides to the question that I generally talk to him somewhat as follows after getting, if possible, a positive slide. Gonorrhea is a disease which it may take anywhere from three weeks to three years or more to recover from. Sometimes it can be aborted.

[1] Read before the Boston Society for Medical Improvement, December 31, 1900.

If successful, that means that a patient is under treatment for from two to six weeks. It is best to treat the case twice a day during the first week or ten days, and the patient uses an injection himself two or three times a day for two or three weeks more. By this method the patient will probably be more comfortable, have less discharge, and get well somewhat more quickly and with less danger of complications. It is not certain that the disease will stop short. It probably will not. If a patient thinks that he cannot give up so much time at first, I tell him that I can give him some medicine and see him perhaps twice or three times in the first week, and then once a week for as long as it takes to effect a cure.

There are many advocates of very many injections in abortive treatment. Personally I have come to believe in only three, nitrate of silver, permanganate of potash and protargol. In the very early stages the disease is confined to the anterior urethra and an injection that will reach that part of the canal is all that is required. I have been more successful with nitrate of silver than with anything else, used as follows: First, have the patient empty his bladder. This washes out the urethra as far as any discharge goes, but leaves some urine in it. As urine combines with nitrate of silver and precipitates some of the silver, I next irrigate with plain boiled water. An ordinary McElroy glass syringe with a blunt end serves very well for this purpose. Strip the penis gently to get out all the water possible. Next inject a syringeful of the silver solution. If the lips of the meatus are puffy, I use a solution of a strength of 1 grain to the ounce. If there is no evidence of very active inflammation I use 2 grains to the ounce. This should be held in for about a minute, when it should be allowed to escape and the urethra should again be washed out with water. Do this twice the first day. Increase the strength of the solution to 2 grains to the ounce the second day, and the next day increase to 3 grains to the ounce. Higher than this it is unwise to go. A few years ago I used to increase the strength of the solution until I was using from 6 to 8 grains to the ounce, but I had 2 cases which had acute exacerbations follow the higher strength. This has never happened where I did not go above 3 grains. The weaker solutions are just as efficient. In the cases I speak of there was scanty urine, backache, headache and a temperature of 103° to 104°. They had to go to bed for several days. There is usually some scalding with the first one or two injections, but nothing unbearable, and after two days patients usually do not complain. Scalding on micturition often ceases after the first injection. The discharge becomes thin and watery after a few days, and often ceases after five or six days. It returns if the treatment is then discontinued, so that it is best to continue the injections for several days more, gradually decreasing the amount of nitrate of silver. If at the end of ten days there is no discharge, let the patient use an injection of permanganate of potash, 2 grains to 16 ounces of water. He should begin by using it twice a day and continue to use it for two weeks or so. When permanganate of potash is used from the beginning instead of nitrate of silver it is best to irrigate with a large amount of a weak solution rather than with a little of a stronger one. One to 4,000 is strong enough. In my hands a Kiefer nozzle has not been satisfactory, and I use a No. 6 English soft-rubber catheter attached to the nozzle of a douche bottle. With the bottle at an elevation of not more than 3 feet the solution has not force enough to get back into the bladder, but flows forward very readily around the small catheter. A soluble lubricant should be used for the catheter. A quart of this solution as hot as can be borne comfortably should be allowed to flow in and out, and where possible it should be done twice a day. This should be kept up for ten days, and then the patient should take injections himself for ten days longer.

Where it is impossible to see a patient as often as these two methods require protargol is a safe injection to let him use himself. A ½% solution is as strong as it is best to begin with, and if there is any great amount of scalding this should be diluted. An ordinary 2-drachm syringe should be used and the injection retained for at least three minutes. Ten minutes is better, but few patients will do it. This should be repeated three times a day for the first ten days, and then at longer intervals until a cure is effected.

With all three of these methods it is often necessary to give a mild astringent injection at the end to get rid of the final glueing together of the lips of the meatus in the morning. For this purpose the following prescription is useful: Sulphate of zinc from 4 to 8 grains, fluid extract of hydrastis ½ ounce, and rose water up to 4 ounces. Strong solutions of silver nitrate applied through an endoscope, or strong solutions of permanganate or corrosive sublimate by injection will rarely cut a gonorrhea short. They are very painful, are apt to lead to serious complications, and are so seldom of any benefit that they are justifiable only under extraordinary circumstances.

If the patient presents himself only after the disease has been fully developed for several days, and there is a thick yellow discharge with scalding, painful erection, etc., there is no use in trying to abort the trouble. If an injection is used at all it should be very mild. It is usually safest to give no local treatment for a time, but rely on medicine. The remedies which are useful, or are said to be useful, in gonorrhea are reckoned by hundreds. As the gonococcus grows in an alkaline medium, drugs to render the urine alkaline would seem to be theoretically contraindicated. The citrate and acetate of potash are useful, mainly, in that they make a patient thirsty. The same result can be accomplished by making him drink water as a medicine. If it does not upset his digestion at least 2 quarts a day should be drunk. Compound salol capsules are good and should be taken after meals and before going to bed. They give about the same results as sandal oil, but without the backache which that so often causes, and they do not as often disagree with the stomach. Methylene blue is also of some use. It is necessary to see that you get methylene and not methyl blue, as the latter has no effect. It is best given in capsules containing 1 grain of methylene blue, 1 drop of oil of cassia, and 1 drop of oil of sandal wood. Three capsules a day is usually as much as a patient can take, and at times the dose has to be reduced to 2 after forty-eight hours. More causes very frequent micturition and tenesmus. The urine is green, and stains the clothing if allowed to come in contact with it. Urotropin has not done as well as it was at first hoped it would. Given in large doses it causes great scalding. Where the bladder has become infected and there is a dirty alkaline urine

it is extremely useful and often accomplishes very prompt results. Salol is indicated in the same class of cases as urotropin, but is not quite as efficient as urotropin as a urinary antiseptic, while it has the same disadvantage of causing scalding when given in considerable amount.

As to diet, if we except peppery and spiced foods there are few things which do harm. A simple diet is best, especially when taking medicine which is liable to upset the stomach. Nothing with any alcohol in it should be allowed, and ginger ale is just as bad on account of the pepper in it. I have seen a case which was doing well lighted up as badly by a bottle of ginger ale as by a bottle of beer.

Other things being equal, the quieter a person keeps the better he will do. Bicycle and horseback riding should especially be avoided. Keeping the bowels open and a hot bath before going to bed lessens the tendency to chordee. It should be impressed upon patients that all sexual excitement is bad for them. They should be told to handle the penis as little as possible, and not keep stripping it to see how much of a drop they can find. A suspensory bandage lessens the liability to epididymitis, and should be worn from the beginning of the trouble. If inflammation should occur, rest in bed and an ice bag give the greatest relief. In patients with a narrow meatus it is often advisable to cut it at the beginning, as it is not possible to give injections satisfactorily unless there is a fairly good opening.

It must always be borne in mind that while an injection can cure a discharge it can also keep one up. In obstinate cases it is occasionally surprising to see how quickly they will clear up when all treatment is stopped. An astringent injection in the early stages of a gonorrhea is unjustifiable. It cannot kill the gonococci nor materially retard their growth. It does often give a false sense of security which later events prove was wholly unwarranted.

The idea that it is not well to do anything for a gonorrhea except give citrate of potash in large doses is fortunately passing away, though in a certain class of dispensary practice I often come to the conclusion that there is a great deal of truth in what one of my instructors once said to me when I asked him why he did not give injections. His reply was, "What is the use? Most of them drink it and the rest squirt it into their bladder."

GONORRHEA IN WOMEN.[1]

BY W. L. BURRAGE, M.D., BOSTON.

AT the outset it is well to bear in mind some of the characteristics of the gonococcus. It has been shown that the gonococcus is somewhat dainty in his diet and habitat. He requires air and he thrives best in an alkaline medium. He lives in columnar and not in pavement epithelium, and, needing oxygen, he does not as a rule go far from the surface. The phagocyte is not the special enemy of the gonococcus, and when the latter ceases to exist it is because he cannot find food and surroundings to his liking rather than because he has been eaten by the phagocyte.

In the course of the inflammatory process set up by the gonococcus the cylindrical epithelium, in which the germ has its home, is cast off and thus the process tends to cease. As shown by Bumm, gonorrhea is essentially a disease of the epithelial layers.

In considering the different portions of the genital tract of the female that are most frequently affected by gonorrhea, we naturally look for those where there is cylindrical epithelium. At the mouth of the urethra are the racemose glands of Skene. These are lined with cylindrical epithelium. In the urethra, which, to be sure, is lined with pavement epithelium, there are mucous crypts which correspond to Littré's glands in the male, and the mucous membrane of the urethra is in folds except during urination, and thus furnishes lurking places for the cocci. The canal of the cervix has many Nabothian glands with walls of cylindrical epithelium, and the glands of Bartholini are also lined in the same way. The vulva, vagina and intravaginal cervix are covered by pavement epithelium, and the vaginal secretion, made acid by the lactic-acid bacteria of Döderlein, is inimical to the life of the gonococcus and other pathogenic bacteria. The uterine canal from the external os to the openings of the tubes is lined with a simple layer of ciliated cylindrical epithelium. In the cervix there is a submucous layer, but in the body of the uterus the utricular glands rest directly on the muscle. These uterine glands are all on the surface, and are shed to a greater or less degree at the catamenia. There are no glands in the tubes, but the walls of the tubes are in folds and are pouch like, thus affording tarrying places for the cocci. The external os, the internal os, and the isthmus of the tube are narrow paths which may serve as barriers to the progress of the gonococcus, so also the neck of the bladder and the sphincter ani assist in shutting out disease from the bladder and rectum.

A majority of authors give the following as the most frequent seats of chronic gonorrhea in the order of frequency: Urethra, cervical canal, Bartholini's glands, uterus, tubes, vulva, vagina, and bladder and rectum. Vulvitis and vaginitis are rare except in certain acute cases and in children. In very young women, in those with delicate mucous membranes and light hair, and where the mucous membrane is succulent, as in pregnancy, gonorrheal vaginitis is more common than it is in women who have intact and firm epithelium in the vagina.

Experimentally, Bumm found that the period of incubation of acute gonorrhea was twelve hours; in twenty-four hours the attack was well established. Clinically acute gonorrhea in the female is much less frequent than in the male. The disease is not, as in the male, always preceded by a period of acute invasion, the symptoms of which necessarily attract the attention of the patient and the physician, and for this reason gonorrhea in woman is often overlooked. The symptoms and signs are for the most part those of subacute or chronic gonorrhea from the start.

The frequency of chronic gonorrhea in women has excited a great deal of discussion ever since Noeggerath published his first paper on the subject in 1872. He stated that 80% of all gynecological cases have latent gonorrhea. Sänger, from an examination of 1,930 cases, both in hospital and in private practice, diagnosed gonorrhea in 12%, and this was in the eighties, after the discovery of the gonococcus by Neisser (1879). Sänger's percentage seems to be a fair one for all cases, and is pretty generally adopted

[1] Read before the Boston Society for Medical Improvement, December 31, 1900.

by writers on this subject. In clinics made up largely of prostitutes the percentage of gonorrhea is necessarily higher, whereas in a better class of private practice the percentage is lower.

The diagnosis is made by the history, by the clinical course, by the appearance of the genital organs, and by the detection of the gonococcus in the discharges. Until recently it has been necessary to rely on the finding of the diplococci in the pus cells, using the Gram method of decolorizing. Now the bacteriologists have succeeded in cultivating the gonococcus outside the body on human hydrocele agar, and Neisser and Bröse and other prominent workers in this field are agreed that cultures should take the place of cover-glass preparations in the diagnosis of gonococcus infection.

From the examination of cover-glass specimens taken from a total of 2,107 cases by Schwartz, Goll, Neisser, Weinrich, Van Schaick and Bröse and Schiller, all of the cases giving the clinical history of gonorrhea, the gonococcus was found in 23%.

The relatively small proportion of cases in which the gonococcus is found makes diagnosis by bacterial methods alone extremely uncertain, and the absence of the coccus is no proof that gonorrhea is not present.

O. Bodenstein considers the diagnostic points as to chronic gonorrhea to be as follows: (1) *a.* History of ophthalmia neonatorum in children of the patient; *b.* former ardor urinæ; *c.* gonorrhea in the husband. (2) Disease of Bartholini's glands. (3) A reddened urethral orifice. (4) Erosions of the cervix. (5) Involvement of the urethra.

P. Bröse and H. Schiller think the clinical course more important than finding gonococci in the secretion from the urethra. They found the gonococcus in only 20% of their chronic catarrhal cases. The signs they consider important are swelling of the urethral meatus, stricture of the urethra, condylomata, inflammation of Bartholini's glands, maculæ gonorrhoicæ of Sänger, tissue defects and scars in the vulva, vaginitis maculosa and granulosa.

A great deal of stress has been laid of late on the appearance of the vulva. A reddened and puffy condition of the mouths of Skene's glands, with a small amount of secretion to be expressed from them, is a common condition. Condylomata are present in patients who are uncleanly, but they are pretty constant in gonorrhea also. A purplish areola like a flea bite around the orifice of one or both of Bartholini's glands — the macula gonorrhoica of Sänger — is often seen.

Stricture of the urethra in the female is by no means as rare as it has been supposed to be, and with the frequent use of the cystoscope our ideas of the pathology of the affections of the urethra and bladder are gradually undergoing a marked change. Chronic endometritis — a catarrhal alternating with a purulent form — is very commonly met with, and pyosalpinx is one of the late sequelæ. Gonococci are found in 20% of these pyosalpinx cases. Gonorrheal cystitis and proctitis are frequently seen in the clinics of many observers. More accurate observations with properly conducted bacteriological tests are especially needed in these diseases.

It is important that a patient who is about to be examined for gonorrhea should not cleanse the vulva and vagina with douches, and that she should not have passed her urine for several hours, otherwise it is often difficult to get secretion from the glands and the urethra. It is sometimes better to examine near the menstrual period, because at that time the congestion of the uterine organs increases the discharges, and it is probable that more gonococci are thrown off. Here we may find an explanation for the popular belief that a man will contract gonorrhea from intercourse with a woman during her menstrual period. Relatively few gonococci at the intermenstrual time may be multiplied into many at the menstrual epoch.

Too great care cannot be taken by the physician in examining cases of suspected gonorrhea. After the vulva has been inspected and its condition noted, and after cultures or cover-glass specimens have been taken, the examining finger, preferably covered with a thin rubber cot, should be anointed without contaminating the remaining lubricating medium. I use Lubri-Chondrin from collapsible tubes. It is very important not to introduce a catheter or sound into the bladder or uterus, and before making a rectal examination, the vulva and nates should be carefully cleansed with an antiseptic solution, and the examining hand thoroughly washed and a new cot put on the finger. After use, the instruments and the cots which have been employed should be boiled and the hands given a special washing and scrubbing in an antiseptic solution.

There has been considerable discussion whether there is any such thing as latent gonorrhea. Taylor, of New York, held that the gonococcus dies and leaves behind it a chronic inflammation. Thorburn, of England, studied 81 families in his practice, in which there had been 33% of gonorrhea in the husband previous to marriage. Taking all the cases of abortion, sterility, uterine and pelvic inflammations and living births, he found that the infected showed no difference from the non-infected, and in the pelvic inflammatory cases there was a slight preponderance on the side of those who had not had previous gonorrheal infection.

From a clinical point of view every physician of experience has had in his practice men who have had gonorrhea previous to marriage, and have subsequently had families of healthy children, and their wives have been free from uterine disease, so that in some cases at least gonorrhea must be absolutely cured.

As causative influences in the production of uterine disease, we must not lose sight of sepsis following labor and abortions, especially induced abortions, to say nothing of unclean uterine treatments — often unwittingly septic — at the hands of physicians.

On the other hand, Wertheim, Finger and Haberda proved by inoculation experiments that a chronic gonorrhea can cause an acute gonorrhea in another person. Wertheim thinks that the reason that it is often difficult to identify the gonococcus is because only the young cocci take the stain and the old ones do not. Toulon in 1894 noted a degenerated type of gonococcus, which is unrecognizable by ordinary methods of examination. It was seen in cultures of gonococci which were from seven to fifty-one days old and consisted of a granular and amorphous mass. By transplantation he got characteristic colonies. Even with a culture fifty-one days old, experiments demonstrated that gonococci may be present in gonorrheal threads, and yet may not be recognizable in cover-glass preparations, but only in cultures. He thought with Wer-

theim that a urethra becomes tolerant to the gonococcus, but that the gonococcus does not lose its virulence when transplanted to a favorable culture medium.

J. Judassohn, of Berne, announces the following conclusions as a result of his study of this question: (1) A mucous membrane affected with chronic gonorrhea may react by exaggeration of the inflammation when there is a multiplication of the gonococci which it harbors or when new gonococci are introduced; (2) a mucous membrane affected with chronic gonorrhea may no longer react in case of multiplication of its own cocci, but may respond by a recrudescence of the inflammation upon the introduction of new cocci; (3) a mucous membrane affected with chronic gonorrhea may enjoy a sort of immunity from acute gonorrhea. He says further that we know nothing of the immunity of the organism on account of the existence of gonorrhea; even a continued chronic gonorrhea in one organ does not prevent an acute inflammatory attack in another, for example, acute epididymitis in chronic urethral gonorrhea.

If the following experiments of Wertheim are verified by other observers they will have an important bearing on the question of the inoculability of gonorrhea. A direct experiment from a pure culture of gonococcus from a gleety discharge of two years' standing gave the following results: (1) Attempted reinfection of the original urethra with this culture was always a failure; (2) the culture when transplanted to a coccus-free urethra produced typical acute gonorrhea; (3) infection from this back again to the original urethra gave a fresh gonorrhea, which, after a typical acute course of five or six weeks, again subsided into a chronic gleet. This explains the fact that an apparently healthy subject of chronic gonorrhea may infect his hitherto unaffected wife, and become again infected from her, that is, the gonococcus, by passing through the new culture of the wife, again becomes virulent for the husband.

In answer to the question, When should the physician advise marriage after gonorrhea? Kromayer states that a man may marry when the urethritis is all gone. The gonococcus may be absent, but it is not safe until the discharge has ceased. If the advice is not taken the husband should urinate before coitus, there should be only one coitus in twenty-four hours, and the wife should take a douche after it. Frequent coitus, because of the increased congestion of the sexual organs and the destruction and bruising of the epithelium, increases the danger of infection.

If we are called upon to pronounce when a woman is entirely free from the danger of transmitting gonorrhea, it is at once apparent that we have to face a more complicated problem than we have in the case of gonorrhea in the male, because of the many possible lurking places for the gonococcus in the sexual organs of the female. As a practical matter we may say that a woman is cured of gonorrhea when there are no signs of chronic inflammation about the uterine organs, and when two or more negative cultures have been taken from the urethra and cervical canal.

The treatment of gonorrhea in women cannot be considered at length in a paper of this character. It must suffice to say that the treatment varies according to the structures which are attacked. In the more acute stages, when the parts are hypersensitive, douches and extreme cleanliness are to be advised by way of local treatment; in the chronic stages vaginitis is most successfully treated by cleansing the vagina with an antiseptic solution and packing it with cotton tampons soaked in medicated solutions, or with dry cotton dusted with an antiseptic or non-irritating powder. In this way the folds are taken out of the mucous membrane, and the applications come into most intimate contact with all parts. As a germicide protargol, in solutions of from 1% to 5%, seems to be displacing nitrate of silver as the standard remedy, and has given better results than the many other salts of silver. I have found vaginal suppositories of protargol useful and efficacious, also vaginal suppositories of ichthyol, as well as the use of the latter drug with glycerin on cotton packings.

In the treatment of chronic urethritis applications to the mucous membrane of the urethra through a small cystoscope of solutions of nitrate of silver, protargol and ichthyol, and also the use of urethral suppositories of the same drugs, have given the best results. Stricture of the urethra is best treated by gradual dilatation with urethral sounds, although rapid dilatation, the patient being under ether, has often given satisfactory results. Skene's glands are treated by similar applications made with a fine wire applicator wound with cotton, and in intractable disease of these glands it is necessary to lay them open into the lumen of the urethra.

The treatment of cystitis, endometritis, salpingitis and proctitis due to the gonococcus does not differ from the treatment of these affections when caused by other bacteria.

The treatment of gonorrhea should be persisted in until the disease is thoroughly eradicated.

TREATMENT OF CHRONIC GONORRHEA.[1]

BY GARDNER W. ALLEN, M.D., BOSTON.

In some cases of gonorrhea a more or less copious, thin, mucopurulent discharge persists for a long time in spite of all efforts to control it. There is an absence of subjective symptoms; in fact such cases are often mild from the beginning; the mucous membrane seems flabby and lacking in tone, showing little tendency to respond to remedies. These are cases of chronic diffuse urethritis. They are often aggravated by active local measures and over-treatment must be carefully avoided.

But, ordinarily speaking, gonorrhea may be said to have reached the chronic stage when the inflammation has become localized at one or more points along the course of the urethra. The discharge, commonly called gleet, is very slight, and the urine is transparent, but contains shreds of mucus and pus. The points at which the subsiding inflammation most commonly lingers are the penoscrotal angle and that portion of the pendulous urethra just anterior to it, the bulbomembranous junction, the prostatic urethra and much less frequently the fossa navicularis.

The tissue changes following an acute gonorrhea, which determine the localization of the disease at these points, have an important bearing on treatment. The mucous glands or follicles of the urethra are particularly numerous about the penoscrotal angle and just anterior to it. They are very liable to be involved in the inflammation together with the tissues about them

[1] Read before the Boston Society for Medical Improvement, December 31, 1900.

and the entire submucous layer surrounding the urethra, which becomes infiltrated with round cells and shows a tendency to cicatricial contraction. In other words, this is a very common seat of stricture of large calibre complicated with inflammation of the mucous glands. The submucous layer about the deep bulbous portion of the urethra close to the anterior layer of the triangular ligament is also very subject to deposit of granulation tissue with contraction, and here we are more likely to have strictures of small calibre, either soft and easily dilatable or very dense and tough. In the posterior urethra the tendency to stricture formation does not exist, but the follicles of the prostate may be involved and the inflammation not infrequently extends up the ejaculatory ducts into the seminal vesicles.

In the treatment of these conditions the objects to be aimed at are the removal of fibrous deposits, the restoration of the thickened and rigid mucous membrane to approximately its original soft and elastic condition, and the cleaning out of diseased follicles and glands.

The first principle of this treatment is dilatation; dilatation of the anterior urethra to check the cicatricial contraction, cause the absorption of the morbid deposit and open up the follicles so that medicated solutions can penetrate them, and dilatation of the posterior urethra in order to open the follicles of the prostate in the same manner and to stimulate circulation in the passively congested mucous membrane.

Ordinary dilatation by means of sounds is often unsatisfactory, chiefly because in many cases it cannot be carried far enough to accomplish results and because it is apt to cause a good deal of irritation and reaction. To cut the meatus sufficiently to admit large sounds is an operation which, although sometimes necessary, should be avoided if possible. By means of dilators which can be passed through a moderate-sized meatus the urethra can be stretched to a point far beyond what is possible with the largest sounds and yet cause little or no reaction. This dilatation may be done as gently and gradually as need be at successive visits without any of the discomfort caused by passing a snug-fitting sound through a rigid and unyielding urethra, perhaps painfully distending the meatus at the same time.

For the purpose of stretching the urethra the four-branched dilators of Kollmann are the best. A straight instrument is used for the anterior urethra and a curved one for the posterior. In this way only a portion of the urethra is dilated at a time. The urethra is much more tolerant of extreme dilatation at one point than of a less degree applied throughout its length. It is surprising how little pain at the time and how little subsequent reaction are experienced in cases where for special reasons it seems advisable to dilate to what might be considered an extreme degree, that is, to 40 or more. Ordinarily we stop several sizes short of this.

After dilatation the local application of various remedies is effected by means of injections or irrigations, and later the urethra is inspected through the endoscope and local applications made under control of the eye to such points as require them.

The course of procedure in an average case of anterior urethritis would be somewhat as follows: To begin with, when the meatus is very narrow it should be cut to a moderate degree, say to 26 or 28, as the calibre of the dilators with the rubber cover is about 23 or 24, and it should be possible at any time to use a fair-sized endoscope. If the patient object strongly to meatomy, dilatation may be fairly well done with an Otis urethrotome without the knife. First, an endoscopic examination may be made to aid diagnosis. Eroded or granular patches, inflamed follicles and rigidity of the mucous membrane can be plainly seen. With a bulbous bougie any narrowing, if of sufficient degree, can be detected and located. It is well to learn as much as possible of the topography of the urethra before using the dilator, although this instrument also is useful in diagnosis as well as in treatment. It is passed well down and opened by slowly and gently turning the screw. Should there be little or no narrowing of the urethral calibre it can be screwed up easily to a high point without pain. When, however, there is stricture a sense of resistance is noticed and considerable force is required in turning the screw and the patient complains of pain. At this point, of course, we stop and either screw down the instrument and remove it or leave it in a few moments. Having removed it, the urethra should be washed out with a solution of corrosive sublimate, potassium permanganate or anything else that may seem advisable, or we may inject protargol. This drug may be used in these chronic cases in solutions of 10% or even 20% without pain or reaction of consequence, and works extremely well. I generally inject about half a drachm into the bulbous urethra, and while holding the meatus tightly closed, rub it in thoroughly from the outside. For the first few days after dilatation, while the follicles are still wide open, the patient should use an injection of bichloride, silver nitrate or permanganate twice a day. This treatment may be repeated in a week, or the endoscope used, according to circumstances. In case of stricture this must be gradually dilated at weekly intervals until practically done away with before the endoscope will be of much use. For local applications through the endoscope, nitrate of silver in solutions of a strength of from 3% to 10% gives the best results.

In the deep bulbous and prostatic portions the curved dilator is used. When the follicles of the prostate are involved massage is of great assistance. First, the patient passes his water or part of it, and its appearance is carefully noted, for it furnishes the best guide to the progress of treatment. Then, with some fluid in the bladder, either part of the urine held back or a few ounces of sterilized water injected after micturition, the prostate is thoroughly massaged by the finger in the rectum. The patient now urinates again, entirely emptying his bladder. This urine or fluid is also carefully inspected at each visit, especially with regard to the presence in it of the short, ciumpy shreds which come from the follicles of the prostate. Then the posterior dilator is passed and screwed up slowly as far as the patient can bear without discomfort, left in a few minutes, removed, and an injection of permanganate, silver nitrate or protargol thrown in. This may be repeated once a week. As a rule no treatment is required in the intervals.

When the seminal vesicles are involved, stripping or massage of these organs is done in connection with the treatment just described. Sometimes a chronic discharge proceeds from the vesicles alone. In this case treatment is confined to them, and stripping is all that is required.

So it appears that when gonorrhea has become localized in the deeper structures of the genito-urinary tract, energetic measures are called for. Time and perseverance are required. Sometimes little improvement will be noticed, the discharge remaining about the same, being kept up perhaps by treatment. In such cases permanent improvement may be expected after the active local measures have been brought to an end. And in cases of doubt as to whether this local treatment has been sufficiently thorough, it is well to suspend treatment for a time and note how much improvement follows and how permanent it may prove to be.

THE SEMINAL VESICLES IN GONORRHEA.[1]

BY CHARLES L. SCUDDER, M.D., BOSTON,

Surgeon to the Massachusetts General Hospital Out-Patient Department; Assistant in Clinical and Operative Surgery, Harvard University Medical School.

SEMINAL vesiculitis may be either acute or chronic. The occurrence of acute seminal vesiculitis during the course of an acute gonorrheal urethritis is rare. In 400 cases of gonorrhea, 160 of which cases were acute, there were 32 cases of prostatitis, 1 case of vesiculitis, and 15 cases of prostatitis and vesiculitis. These were cases observed by Colombini in 1897, and reported.[2]

Direct gonorrheal infection, that is, the extension from the urethra along the ejaculatory duct and into the vesicle, is therefore extremely rare. Such inflammations are very acute and of an extreme type. The contents of the vesicle become purulent, the vesicle wall and the perivesicular tissues are involved, and occasionally the peritoneum, which lies close to the summit of the vesicle, is also implicated. There are a few cases reported in which a general peritonitis has resulted from such peritoneal involvement. One vesicle alone is usually involved in the inflammatory process.

The element of germ infection in these cases is of very great importance. Beside the gonococcus in certain other cases presenting the signs of an acute seminal vesiculitis, the only germ found present has been the colon bacillus. It is probable that infection may take place, therefore, not only by continuity along the surface of the urethra through the seminal duct, but by direct invasion from contiguous tissues, such as the rectum.

The symptoms of acute seminal vesiculitis are almost wholly inflammatory in character, characterized by fever, pain and tenderness. The pain may be referred to the suprapubic region, to the sacrum, to the spermatic cord, to the scrotum, to the kidney, to the bladder, or to the urethra. The tenderness may be referred to the suprapubic region, where muscular rigidity may be evident, or to the region of the seminal vesicles by rectal palpation.

The examination of the urine in these cases of acute vesiculitis is of the greatest importance. While purulent material is collecting within the sac of the vesicle, the acute symptoms are at their height. Immediately upon the emptying of the vesicle the acute symptoms subside, and at this time, when the symptoms have diminished in severity, pus appears in the urine. So that while the acute inflammatory process is at its height the urine may be nearly clear, but it becomes purulent with the decrease of the symptoms and the escape of pus from the vesicular cavity.

The involvement of the perivesicular tissues is determined by palpation of the vesicles by rectum. The vesicles, instead of being easily detected in their swollen condition, are more or less obscured by a very great general swelling in their immediate neighborhood, and the edema or bogginess to the palpating finger extends over a wide area. When pus accumulates in these perivesicular tissues it may find an exit either into the peritoneal cavity or into the bladder, or into the rectum, or it may become absorbed. A few cases of pyemia have been reported which originated in an acute seminal vesiculitis. Along with very acute seminal vesiculitis, the prostate is usually somewhat enlarged, that is, congested, and pressure upon the prostate will cause pain. The maximum degree of tenderness is elicited when pressure is made over the seminal vesicle itself.

Treatment of acute seminal vesiculitis. — At the outset, measures directed toward checking the inflammatory process should be taken. If pus is present it should be evacuated either by incision and drainage through the rectum, or by incision and drainage through the perineum.

Chronic seminal vesiculitis. — Chronic vesiculitis is due either to indirect gonorrheal infection, resulting from an extension to the vesicle of inflammations connected with urethral lesions, the source of which was gonorrhea, or to tubercular infection.

Symptoms of chronic seminal vesiculitis of gonorrheal origin.[3] — No inflammatory symptoms are present. The symptoms are functional or neurotic in character. Complaint is made of perverted sexual desire, irregular seminal emissions and neurotic sensations. Certain mental symptoms may be present in these cases which are quite characteristic.

Many cases of so-called gleet may be found to be due to a chronic seminal vesiculitis, and many cases of chronic seminal vesiculitis may be the occasion of many of the neurotic and hypochondriacal symptoms seen in genito-urinary practice.

The treatment by massage of the vesicles should be instituted before resorting to extirpation. Extirpation of the sac of the seminal vesicle should be reserved for extreme cases, associated with serious or severe subjective symptoms.

The operative routes to the seminal vesicles.[4] — There are three routes by which the seminal vesicle may be reached, the inguinal, the perineal, or the sacral.

The steps of the inguinal operation are as follows. The descriptions are those given by Bolton: (1) Incision over the inguinal canal parallel with Poupart's ligament to scrotum; (2) splitting aponeurosis of the external oblique over the canal, separation of vas, and enucleation of testis; (3) ligation of deep epigastric vessels and incision of transversalis fascia; (4) separation of peritoneum from iliac fossa wall and pelvis and bladder along the course of the vas deferens to the ureter; (5) division of vas, its withdrawal from around the ureter; (6) separation of vas and vesicle from base of bladder and from prostate and their removal.

[1] Read before the Boston Society for Medical Improvement, December 31, 1900.

[2] Centrbl. f. die Krankh. d. Harn. u. Sex. Org., 1897, S. 521.

[3] Eugene Fuller: Disorders of the Male Sexual Organs.

[4] Bolton: Journal of Genito-Urinary Diseases, vol. xvii, 1899, p. 551.

The perineal operation is done in the following steps: (1) A curvilinear incision from one tuberosity of the ischium to the other, crossing the perineum about an inch in front of the anus and dividing the insertion of the sphincter ani into the tendinous centre of the perineum; (2) division of the anterior fibres of the levator ani and exposure of the rectum and prostate, and the separation of these till the base of the prostate and lower ends of the vesicles are reached; (3) division of one or both ejaculatory ducts at the base of the prostate by a transverse cut, seizure of the vesicle and its forcible extraction.

The steps of the sacral operation, using the Rydygier incision, are these: (1) The Rydygier incision, namely, beginning just behind the anus the oblique limb is carried up and slightly outward to the level of the junction of the fourth and fifth sacral vertebræ, dividing the tissues attached to the side of the coccyx and last piece of the sacrum. The transverse limb crosses the lower end of the sacrum at the upper end of the oblique. A few strokes of the osteotome divide the sacrum and allow the triangular flap so formed to be turned down, exposing the rectum. The rectum is next displaced to the right and the prostate exposed and then working from below upward the base of the bladder with the attached vesicle and vas is easily brought into view, but at some depth. Moderate distention of the bladder brings the vesicle nearer to the surface and makes its removal a matter of no great difficulty. (2) Displacement of the rectum and exposure of the prostate and base of the bladder. (3) Isolation of either or both vasa and vesicles directly under the eye and their removal.

GONORRHEAL PROSTATITIS.[1]

BY JOHN BAPST BLAKE, M.D., BOSTON.

WE are to consider briefly in this paper inflammatory processes involving the prostate, which accompany, complicate, and are dependent upon a pre-existing or coexisting gonorrheal urethritis. Such processes may vary markedly in duration, intensity and extent.

In duration they may be either acute or chronic, and last from three days to three weeks, or from months to years. In extent they may be limited to prostatic follicles, may involve the entire organ, or may penetrate the capsule and extend to the surrounding tissues. In intensity they may be of any degree, from a simple congestion with vague symptoms to rigors, fever, prostration and perhaps death.

It is obvious, therefore, that the clinical picture of gonorrheal prostatitis may be a many-sided one, and it should not be forgotten that in all its aspects, particularly in symptomatology, treatment and prognosis, it is further modified by the fact that it rarely exists unaccompanied with other complications; a posterior urethritis always precedes it; in the acute cases cystitis in some degree almost invariably accompanies it, and in the chronic condition it is with equal frequency associated with vesiculitis.

Anatomy. — The prostate is a roughly pyramidal musculoglandular organ, directly continuous with the neck of the bladder, situated behind and slightly below the pubes, from which it is separated by the cellular tissue of the space of Retzius. Posteriorly, only a fold of rectovesical fascia intervenes between it and the rectum. It is enclosed in a thin but firm fibromuscular capsule. It is about $1\frac{1}{4}$ inches deep, $1\frac{1}{2}$ inches wide, and $\frac{3}{4}$ inch thick, and its apex touches the posterior layer of the triangular ligament. The ancient and time-honored simile likening its shape to a chestnut is a description which applies with considerable accuracy as well to the comparison as to the gland itself. The mass of the prostate lies behind the urethra, which in this position has an almost vertical direction. The prostate consists of two parallel lobes connected posteriorly by a bar or collar. Normally a distinct third lobe does not exist.

A section shows a series of more or less complicated lobules, or glands, opening by from fifteen to thirty-two ducts into the prostatic sinus of the urethra. Five-sixths of the organ is glandular substance. Muscular fibres surround each lobule, of which there are forty or fifty. Elastic fibres keep the mouths of the ducts closed. The connective tissue is amply sufficient to furnish the necessary support to the glandular structures. The muscular substance is arranged primarily to compress the prostate, not to act as a vesical sphincter.[2]

Frequency. — Accurate statistics of the frequency of gonorrheal prostatitis are not obtainable by the writer. Montagnon and Eraud, quoted by Finger, say that the prostate is affected in 70% of all posterior urethrites. It is difficult to perceive how a posterior urethritis of any severity can fail to be accompanied by some degree of prostatic congestion, and if so it is only a question of opinion as to the amount of congestion which merits classification as a separate entity. Statistics of frequency will therefore vary with the accuracy and thoroughness of the observer; with the habits, mode of life and general condition of the patient, and with the character of the treatment. If the prostate be examined by rectum as a routine measure in every case of posterior urethritis the 70% given above will certainly be found not excessive.

A well-defined prostatic abscess, however, as the result of gonorrhea, is not a common occurrence. The following figures are taken from the card catalogue of the Boston City Hospital for the years 1881 to 1896: Abscess of prostate, 11 cases; prostatitis, 37 cases; prostatic hypertrophy, 241 cases. Of the 11 cases of abscess at least 3 were not obviously of gonorrheal origin, and at least 5 of the cases of prostatitis were not distinctly associated with gonorrhea. On the other hand, these figures only denote those cases in which the prostatic element dominated the situation, and do not include those in which it only complicated a more severe condition. They are, therefore, only relative, but emphasize the infrequency of the condition.

Etiology. — Within the past eight years the etiology of most of the complications of gonorrhea has been scientifically established. Among the latest contributions are those of Young, of Johns Hopkins, who has shown that the gonococcus may be the sole cause of acute and chronic cystitis, double pyonephrosis and general peritonitis. I have been unable to find in print the results of similar work upon the prostate.

Infection of the prostate may come by direct extension from the urethra, by the blood or urine (tubercle,

[1] Read before the Boston Society for Medical Improvement, December 31, 1900.

[2] Walker: Johns Hopkins Hospital Bulletin, vol. xi, p. 242.

typhoid) or by continuity of tissue. In gonorrhea it always comes from the urethra and from a pre-existing posterior urethritis. It is evident, therefore, that it may be due either to the gonococcus alone, or to a mixed infection, since we know that many cases of gonorrhea become a mixed infection early in their history. It is to be hoped that the investigations which have explained etiology and pathology of other gonorrheal complications will soon be duplicated in those involving the prostate.

Clinically, a posterior urethritis always precedes a prostatitis, even though the latter be due to manipulations with unclean instruments. Anything which irritates or tends to increase the congestion accompanying a posterior urethritis may act as an exciting cause of a prostatitis. Among many agents may be mentioned alcohol, coitus, prolonged sexual excitement, exposure to cold, forcible and injudicious injections, horseback riding, bicycling, and such violent exercise as running, jumping, etc. The jolting coincident to a railroad journey may be a determining factor.

Prostatitis usually appears at the end of the second or during the third week of urethritis, though it may, of course, come later. It may be worth while to repeat that it may be either acute or chronic, and that the acute cases may be of the type of simple congestion; of inflammation limited to the follicles and perifollicular tissues; of a process involving both follicles and parenchyma and progressing to pus formation of greater or less degree, and, finally, of a process involving almost the entire gland and extending to the periprostatic tissues. The chronic type is almost always follicular, though occasionally it is characterized by one or more small abscesses which develop without most of the typical symptoms. The duration of the acute congestive and follicular types is from three days to three weeks, parenchymatous and purulent from one to three months, and the chronic for months or years.

Congestion. — The beginning of congestive prostatitis may be suspected when the symptoms of an existing posterior gonorrhea increase, and pain and a feeling of soreness and weight deep in the perineum became especially prominent. If under these conditions rectal examination shows a prostate tender or hot or both, further data for the establishment of a diagnosis are not need. An increase in size may or may not be present, and even the increase in pain may be comparatively slight. The urethral discharge will probably be diminished. Under these conditions the patient should be put immediately to bed, bowels moved with salines, the diet made still more bland and hot rectal injections of moderate size given and retained. A hot-water bag may be placed against the perineum. Opium with or without belladonna may be given in suppositories, if the pain increases; and ol. santali will moderate the accompanying cystitis. European writers recommend highly Finger's hollow bulbous rectal tube, through which flows a continuous stream of cold water. It is introduced into the rectum and rests against the rectum.

The symptomatology of prostatic congestion is essentially an exaggeration of posterior urethritis, and its treatment is therefore an extension and elaboration of that of the latter.

Follicular. — In the follicular type the deep perineal distress and pain increase, and may radiate and shoot into the rectum or groin, or be referred to the end of the penis. Micturition is still more affected and tenesmus develops; frequently a drop of blood appears at the meatus, the result of the spasmodic action of the bladder sphincter at the end of the expulsive effort. The prostate is usually increased in size, and often one or more particularly tender spots denote the position of the inflamed follicles. The urethral discharge is usually diminished.

Parenchymatous. — With the involvement of the parenchyma, the increase in size becomes still more marked. The prostate, exquisitely sensitive, projects far into the rectum, causing a continuous, painful and, of course, ineffective desire to stool. Difficulty of micturition increases even to complete retention, and spasm of both urethral and rectal sphincters is almost constant. The general condition of the patient is seriously affected.

Abscess. — The formation of an abscess is almost always accompanied by rigors with marked exacerbations and sharp remissions of temperature, and a sensation of throbbing in the perineum, together with all the symptoms which accompany deep-seated suppuration. Fluctuation can often be discovered by rectal examination. Extreme prostration, suspicions of attendants and physicians, rejection of treatment, and delirium are not unusual. The prostatic abscess may point and break in almost any direction, the most frequent localities being the urethra, the rectum and the perineum in the order named. Occasionally the rupture is in two of these places simultaneously. Segond's classical collection of 102 cases showed rupture into urethra in 64, rectum in 43, perineum in 15, ischiorectal fossa in 8, and also in the groin, the prevesical space, the peritoneal cavity, the abdominal wall and the pelvic foramina. In the City Hospital cases above quoted 4 burst into the urethra and 2 into the rectum. As a rule the cavity granulates and fills rapidly and no further trouble results, but a urinary fistula may remain. This happened in 10% of Segond's group. The abscess cavity may be still further infected from the urethra or rectum with fatal results.

The mortality in prostatitis may be due to a variety of causes. Post [3] mentions 3 cases. One died in three weeks from the beginning of the gonorrhea and one week after the first symptoms of abscess, with fever and delirium. A second died in two months from pyemia and metastatic abscesses in lungs, liver and other organs; and a third from prostatic abscess with double pyelonephritis.

The mortality is variously estimated from 3% by White to 30% by Segond. Apparently different types of cases had been examined.

Retention is present in a large majority of cases; it may be relieved by repeated catheterization; by inserting a small catheter and leaving it in place, or by aspirating over the pubes. Unless we desire to utilize the catheter to facilitate discharge of the abscess through the urethra — as frequently occurs and as is sometimes recommended — aspiration is the method of choice. The surgical treatment is to afford drainage for the pus. If the abscess points into the rectum, after stretching the sphincter and cleansing the lower bowel, the fluctuating point may be incised with a bistoury, or punctured with a trocar, preferably the former. It is questionable whether any advantage is to be obtained by introducing gauze into the incision.

[3] Boston Medical and Surgical Journal, 1887, vol. cxvi, p. 417.

If the diagnosis is established before the abscess points into the rectum or perforates into the urethra, it should be opened through a median or crescentic incision in the perineum; this may involve a deep and rather difficult dissection and a wound not easy to drain effectively. High temperature and chills should cease as soon as thorough drainage is established, and retention is immediately relieved.

Periprostatitis.—Purulent periprostatitis differs only in extent from prostatic abscess. Symptomatology and treatment are practically the same. (It may be regarded as a later stage of parenchymatous inflammation.)

Prognosis. — In congestive and follicular prostatitis the prognosis is good. In purulent parenchymatous and periprostatitis it is guarded and dependent upon the possibility of effective drainage and on the patient's general condition.

Chronic prostatitis may result from a pre-existing acute condition, or may, and usually does, develop from a chronic posterior urethritis. It is usually follicular. Occasionally a chronic parenchymatous condition is found, with the development of numerous miliary abscesses. The symptoms are largely those of chronic posterior urethritis, with the addition of perineal tenderness, and an accompaniment of neurasthenia. The follicular type is characterized by the presence at the meatus of a thick, glairy mucus, which appears after stool or during sexual excitement, the so-called prostatorrhea. These chronic processes are almost invariably associated with vesiculitis and their duration is indefinite. The treatment is that of chronic posterior gonorrhea and of sexual neurasthenia — cold baths, general tonics, healthful habits, and locally, cold sounds, deep injections of nitrate of silver and, in the absence of acute symptoms, massage of the prostate.

GONORRHEAL CONJUNCTIVITIS.[1]

BY CHARLES H. WILLIAMS, M.D., BOSTON.

DR. BRADFORD has asked me to add a few words to the discussion of this subject, in regard to the gonorrheal inflammations of the eyes. It has been estimated that from one-third to one-half of the existing cases of blindness have been caused by gonorrheal inflammations of the eyes, generally as a result of infection of the cornea, and the ulceration and sloughing which often destroy more or less of the cornea. The disease generally occurs in infants, from one to five days after birth, or in young adults, and in almost all cases is caused by carrying to the surface of the conjunctiva some of the diplococci of Neisser (gonococci) either at the time of birth or in the subsequent washing of the infant's eyes, or by dirty fingers, towels, etc., in adult life. Other pyogenic organisms may give rise to a purulent conjunctivitis similar to the true gonorrheal form, so that it is not possible in any given case to say that the trouble must be due to gonorrheal infection without making a bacteriological examination, although in most cases it would be true.

In ophthalmia neonatorum the disease begins with a slight redness of the lids and a watery discharge from the eyes, the swelling of the lids rapidly increases, the discharge becomes streaked with mucus and is soon quite purulent and abundant. Swelling of the lids may be so extreme as to prevent their being opened for proper cleansing or examination except by use of a lid elevator, and the pressure of the lids on the cornea may become so great as to require a canthotomy. The inflammation of the conjunctiva will in time disappear without any serious results to vision, but the principal attention must be constantly directed to the condition of the cornea, to prevent, if possible, the infection of its tissue with the purulent matter.

For this purpose the first and most important treatment is the careful removal of the purulent discharge. This should be done every fifteen minutes or half hour, if necessary, night and day for the few days the disease is at its height, and at longer intervals as the discharge decreases. It is necessary to remove this discharge as thoroughly as possible, taking care that no damage is done to the protecting epithelium of the cornea. It does not make much difference what liquid is used for irrigating the conjunctival sac provided it is not irritating; my own preference is for a warm saturated solution of boric acid, used in quantities of half a pint to a pint at a time, by means of a small fountain syringe and a tube provided with a glass nozzle, with its end drawn out to a tube not over one-eighth inch in diameter, the end being carefully rounded in the flame. This should be cautiously inserted between the eyelids with the end carefully turned away from the cornea toward the upper part of the conjunctival sac, and moved across the lid so that the discharge may be removed from the whole of the conjunctival sac by the warm stream of irrigating fluid. Various forms of hollow lid elevators have been devised in which the fluid enters the shaft of the elevator and is discharged through a series of fine openings at its edge, which rests in the upper part of the sac, but in using any form of irrigating instrument great care must be taken not to injure the cornea.

The eyes of the nurse should be protected from any chance of infection by the spattering of a drop of the discharge into her eyes, and for this purpose a mica shield reaching well up on the forehead and extending to the temples can be used; protectors of this kind are used in sleighing to shield the eyes from the bits of flying ice and snow, and answer the purpose very well.

In the early stages of the disease, both in infants and adults, applications of cold may be made by means of cloths cooled on ice and laid over the eye, with frequent changes as the cloths get warm; but the cold applications should not be continued if any corneal complications arise. Nitrate of silver solutions should not be used in the early stages, but in the later stages of the disease, after the intense swelling of the eyelids has begun to subside and the discharge is more purulent, a 2% solution may be applied to the conjunctival surface and then neutralized with a salt solution, with good results, but nothing should take the place of the constant cleansing away of the discharge by gentle means as often as is necessary. Solutions of protargol, from 20% to 40%, applied to the everted lids in the later stages of the disease will in many cases work well, but it seems to be a less reliable remedy than the nitrate of silver. The edges of the eyelids and the surrounding skin should be protected with vaseline.

[1] Read before the Boston Society for Medical Improvement, December 31, 1900.

In patients who are in poor physical condition the application of heat will often prove better than cold; this can be done by hot cloths of several thicknesses which have been ironed with a hot flat-iron and applied to the eye as soon as they can be borne, or an electrically heated pad, in which the temperature can be well regulated, can be used. The patient should be kept in bed, the bowels well open, and if necessary tonics should be added to a liberal diet.

The danger of corneal complications is greater in adults, especially when they are in poor condition, than in infants, and in some severe cases it may be necessary to do a canthotomy or even to divide the upper eyelid vertically in order to relieve the pressure on the cornea and ensure its proper cleansing and treatment; after the inflammation has subsided the edges of the cut can be freshened and the lid united by fine sutures without any marked disfigurement. If the cornea becomes hazy and a small ulcer forms, continue the irrigation, use 1% atropine three times a day, and hot applications rather than cold. In some cases of marginal ulceration solutions of eserine, one-half grain to the ounce, may be used every four hours, but it must be used with care, and when the ulceration is central atropine will probably work better. With infants, especially in large lying-in hospitals, the number of cases of ophthalmia neonatorum has been much reduced by the prophylactic treatment proposed by Credé; he advised putting two drops of a 2% solution of nitrate of silver into the conjunctival sac immediately after birth, the lids having been first carefully wiped dry with a clean cloth, and care being taken not to get any of the water in which the child is washed into the eyes. In all cases in which there is any suspicion of gonorrheal trouble this method should be followed, also in large lying-in hospitals, but in ordinary cases of private practice it is usually not necessary.

When first seen, especially in adults, if the disease has only affected one eye, the other eye should be at once protected by covering it with a small pad of absorbent cotton over which gauze is placed, cut so that it reaches above the eyebrow and below the eye; this gauze should be fastened to the skin by repeated applications of collodion, special care being taken to make a tight joint at the bridge of the nose, over which some discharge is very likely to find its way. The gauze should be covered with collodion over its whole surface, and if necessary a piece of mica can be inserted in a window cut in the centre of the dressing, as recommended by Dr. Knapp, the cotton pad being omitted; the sound eye can thus be better watched and the patient can look about him.

The patient and all his attendants should be warned of the very infectious character of the discharge, and the necessity of burning all dressings that have been brought in contact with any of the discharge from the diseased eye.

WHEN IS A GONORRHEA CURED?[1]

BY PAUL THORNDIKE, M.D., BOSTON.

WHEN is a gonorrhea cured or ended? No one knows, and yet upon the answer to this question many social and moral problems of the greatest importance depend. We must admit at the beginning that the question cannot be answered. We do not and can never know when a man whose urethra has become infected with a gonorrheal inflammation ceases to be a dangerous person to those with whom he may have sexual relations. We believe we know that many such men do recover, as proven by subsequent experience. Many of them certainly do recover, so far as our present means of ascertaining that fact goes; they do marry and have healthy wives and children. Many others who believe they are well certainly do infect their wives.

Noeggerath, in 1872, in a paper which excited comment throughout the whole medical world stated that men infected with gonorrhea never recovered, and that 90% of these men, when they married, infected their wives. A few years later he formulated his conclusions somewhat as follows: "(1) That gonorrhea in the male, as well as in the female, persists for life in certain sections of the organs of generation, notwithstanding its apparent cure in a great many instances; (2) that there is a form of gonorrhea, which may be called *latent* gonorrhea, in the male as well as in the female; (3) that latent gonorrhea, in the male as well as in the female, may infect a healthy person either with acute gonorrhea or gleet; (4) latent gonorrhea in the female, either the consequence of an acute gonorrheal invasion or not, if it pass from the latent into the apparent condition, manifests itself as acute, chronic, recurrent perimetritis or ovaritis, or as catarrh of certain sections of the genital organs; (5) latent gonorrhea, on becoming apparent in the male, does so by attack of gleet or epididymitis; (6) above 90% of sterile women are married to husbands who have suffered from gonorrhea, either previous to or during married life."

These statements were made as the result of the author's clinical experience, and were made at a time when the gonococcus was still unknown. The discovery of the gonococcus does not seem to have markedly changed the force of these conclusions and when we remember that even in the anterior urethra remnants of the disease (possibly capable of reactivity) may exist and defy our most careful efforts to discover them; when we remember that it has been pretty definitely proved that in the greater number (probably over 90%) of all cases of acute gonorrhea the deep urethra is invaded; when we realize that the seminal vesicle is undoubtedly involved many times for every once that such involvement is discovered; when we think that a gonorrheal pyelitis may occur and continue to exist indefinitely with no knowledge to that effect on the part of its possessor; when we realize that all we can do to combat such a disease is to reach and treat such portions of it as we may with the means at present at our command, and to leave nature to handle the rest of it (no small part in many instances), we cannot be surprised at the character and scope of Noeggerath's statements. Nor can we disprove them except by offering in contravention to some of them, clinical observations and experiences of a character similar to his own. I take it, however, that it was not intended by the gentlemen who arranged this series of papers on gonorrhea, that this one should try to deal in detail with these various statements, nor is it necessary for the purposes of this paper to do so. It makes little difference just how far we, as individuals, are able to acquiesce in these statements

[1] Read before the Boston Society for Medical Improvement, December 31, 1900.

concerning gonorrhea. The medical world is united in realizing that gonorrhea is not the simple disease it was once considered, but is one which often spreads to places where its local treatment is impossible; which very often becomes chronic and sometimes defeats the efforts of the most expert for its eradication; which in very many instances retains its contagious capabilities long after its very existence is supposedly ended.

What can we, as physicians, do about such a state of affairs? We can do two things: (1) We can use every effort to prevent the exposure of innocent women to this infection, and (2) we can teach the rest of the world, both medical and non-medical, the necessity for being similarly careful. Most men have probably had a gonorrhea at some time in their lives. Whether or no we believe that none of these men have ever been cured, we certainly cannot forbid them all to marry; but we can subject all those who come within our reach to the most rigid examination, and then tell them either that we can find no trace of the disease and so believe them safe to marry, or that we have found traces of disease which it is absolutely necessary shall be treated and if possible cured. Most such cases depend upon a definite cause, which can be found and generally eradicated.

In brief, all acute cases should be freed from all traces of discharge, both that visible at the meatus and that showing as shreds in the urine, and should remain so free for a period of months, during which time the patient has lived his usual life, eating, drinking and exercising as he will. In the chronic cases, the *cause* of the discharge, whether it be a stricture already formed, granulating patches, areas untreated and uncured in the posterior urethra, involvement of the seminal vesicles, or any one or more of the many possible causes, must be sought for by one competent to so search, and when found must be treated and cured. This can generally be done, but often takes a number of months for its accomplishment. Having been so accomplished, the patient must pass through a period of probation similar to the one mentioned above. There remain a few cases where the most rigid examination of the whole urethra, prostate and seminal vesicles fails to reveal any lesion to account for the persistent drop or shred. In these cases it is my belief that efforts should be made to re-establish an acute inflammation by judicious local irritation with injections, and then a careful search for gonococci should be made in the discharge thus re-established. Should none be found after a number of examinations, the artificially produced inflammation is allowed to subside, which it should do in two to three days, and the remaining shred or drop be repeatedly and carefully examined for gonococci, preferably by another physician than yourself. If they are not found and the discharge is mucoid in character, the patient must probably be allowed to marry, but must still be told of the risk he runs. (Personally, I believe it to be a slight one.)

Of the various methods and instruments necessary for proper examination of these cases there is no time to speak. Nor is it expedient, for the work is work for the expert and not for the general practitioner. The writer's personal belief may be summarized something as follows:

(1) That the methods of examination at present at our command are fairly adequate to determine in any individual case whether there are still contagious possibilities in that case.

(2) That the methods of treatment at present at our command are fairly adequate for the treatment of those cases where remnants of disease are found.

(3) That all such remnants of disease should be treated whether they contain gonococci or no; and that they can be intelligently treated only after they are found and located.

(4) That there are a few cases where the remnant of discharge persists, but where no cause for its persistence can be found by the writer in spite of many most careful efforts. Some of these cases must probably be allowed to marry with traces of discharge still discoverable; but none such should marry until every possible effort has been made to demonstrate its non-contagious character and until the possibility of future trouble has been explained. It is the writer's custom to have more than one opinion in any case of this kind.

Medical Progress.

PROGRESS IN ORTHOPEDIC SURGERY.

BY E. H. BRADFORD, M.D., AND F. J. COTTON, M.D., BOSTON.

(Continued from No. 5, p. 111.)

CHRONIC VILLOUS POLYARTHRITIS AND ARTHRITIS DEFORMANS.

The former is, according to Schüller,[22] a bacillus affection. Characteristic bacilli were found in 20 cases operated upon by him. The bacilli were found in the fringes and in the synovial tissues. These bacilli were cultivated and produced in guinea pigs a similar process. In arthritis deformans the affection does not attack the synovial membrane, but the cartilage covering the ends of the bone. The affection apparently is one of metabolism. At least no micro-organisms have been discovered. In the former affection Schüller uses guaiacol-iodoform glycerin injections, which are to be repeated. Operative method has the disadvantage that it requires for its completion a long continuous after treatment. In his later cases, thiocol was used instead of guaiacol. The injections are of no use in arthritis deformans. In the latter affection the writer endeavors to treat by giving a diet which is poor in lime, in opposition to what other writers have used. A little milk is given, and under this treatment an increase in the elimination of lime in the urine is observed.

CHRONIC RHEUMATISM AND ARTHRITIS DEFORMANS.

Müller[23] insists on the necessity of a careful diagnosis in these cases. Chronic rheumatism belongs more properly in its treatment to the department of internal medicine. Arthritis deformans needs to be treated by surgical means and gymnastics.

Clement Lucas[24] has collected 20 cases of joint disease in infants, apparently gonorrheal consecutive to gonorrheal ophthalmia. In most of the cases the ophthalmia dated from birth and infection in parturition. The arthritis appears usually in the second or third week. All joints may be affected, most often

[22] Berlin. klin. Woch., 1900, Nos. 5-7.
[23] Zeit. f. orth. Chir., Bd. viii, H. 1.
[24] Transactions of Medico-Chirurgical Society of London, 1899, lxxxii, p. 137.

several at a time, most frequently the knee and the wrist. Duration seems to depend largely on the treatment and cure of the ophthalmia. Usually the arthritis lasts four or five weeks. In 2 cases there was suppuration necessitating operation.

CONGENITAL DISLOCATION OF THE KNEE.

Drehmann claims that this affection, although not rare, has been less written about than congenital dislocation of the hip. The prognosis of treatment if the cases are taken early is much more favorable than in congenital dislocation of the hip, and consists of early forcible reduction of the deformity. The obstacle to reduction is the shortening of the quadriceps; this can be either divided or stretched. The limb should be put up in a plaster-of-Paris bandage in a corrected position.

TRANSPLANTATION OF THE TENDONS.

Lange,[25] in the place of tendon transplantation, that is, the sewing of the tendon of a strong muscle to a paralyzed tendon, substitutes what he calls periosteal transplantation. He considers that the advantage of this is that instead of inserting a strong muscle into a weak tendon, he can insert strong muscles into the desired point of bone, making an attachment where he wishes. He thinks that in this way it may be possible to lay aside apparatus in 80% or 90% of the cases of this deformity. He presents a case of paralytic varus where the tibialis anticus was split and one part stitched to the outer part of the tarsus with excellent result, also a second similar case. In 2 earlier cases the biceps and semitendinosus tendon were transplanted into a quadriceps tendon, without results, owing to the feeble condition of the quadriceps. He, therefore, in 3 later cases connected the tendon of the biceps and the tendinosus with the periosteum of the tibia, making a connection between the tendon of the semitendinosus and of the biceps and the periosteum by strong silk thread, which passed subcutaneously between the patella and the skin to the tibia, and was sewed to the tuberosity of the tibia. The result is reported to have been excellent.

Popper [26] reports successful results of arthrodesis of the knee and the astralagotibial articulation. The patient before the operation was only able to walk on all fours. The operation has also been done successfully in paralytic valgus, and also in the wrist in the case of a paralyzed hand.

PERIOSTEAL TRANSPLANTATION, ARTHRODESIS IN INFANTILE PARALYSIS.

Hoffa [27] recommends arthrodesis, and has practised it in a case where both knees and the astralagotibial articulation were operated on and obliterated. The boy had previously been able to walk only on all fours. The operation has also been performed with success in paralytic deformity of the wrist.

TORTICOLLIS.

Pfeiffer, in a monograph (Berlin, 1900) on the treatment of torticollis, reports 25 operated upon and 13 treated by massage. The birth of these children was in 18 in pelvic presentation; 6 were artificial; 1 foot presentation; 11 the head position, besides 3 cases of turning and 4 cases aided with forceps. The writer is of the conclusion that torticollis from intrauterine position is not common, if it has ever been accurately observed. The most common cause is the tearing of the sternocleidomastoid muscle which takes place in pelvic presentation. The right is the most common side. The most important moment for the injury to the muscles is the turning of the head, the muscular contraction in early attempts at breathing. A hematoma following an injury, and an interstitial fibrous myositis, will call forth a contraction of the muscle. If an improvement is to be seen in the sternocleidomastoid energetic massage will be sufficient, but if induration is obstinate, excision of the callus is desirable. If the muscle is degenerated, open incision is preferable to myotomy. An apparatus correcting position is desirable for awhile.

OPERATIVE TREATMENT OF SPASTIC TORTICOLLIS.

Kalmus [28] describes the result in 95 cases, treated by operation, upon which 118 operations were performed. In 11, the stretching of the spinal accessory nerve was undertaken, 3 were cured. With a section of the accessory nerve, 23 were cured, 20 showed improvement, 4 were but slightly helped, and 1 died of erysipelas. In 15 cases after the resection of the accessory, further operative interference was undertaken: in 13, resection of the cervical nerves followed, in 2 resection of the sternocleidomastoid with a destruction of the accessory. Of those cases on which the cervical nerve was divided, 10 were healed and 3 were benefited. In the same way in those on whom, after the destruction of the accessory, a resection of the sternocleidomastoid followed, cure resulted. Two resections of the cervical nerves without the resection of the accessory resulted 1 cured and 1 improved. In 15 cases the cervical nerves were affected, and 11 of these were healed.

A comparison of this method, that is, the combination of muscle division and resection of the cervical nerve with a previous resection of the accessory, gave better results than in Kocher's procedure, by muscle resection, but the writer thinks that further investigation is necessary. Internal treatment is without benefit. Electricity and massage combined with orthopedic treatment is sometimes successful.

Recent Literature.

Description of the Human Spines Showing Numerical Variation in the Warren Museum of the Harvard Medical School.[1] By THOMAS DWIGHT, M.D., LL.D., Parkman Professor of Anatomy in the Harvard Medical School. Published by the Society. 1901.

In a monograph of 75 quarto pages Professor Dwight describes a collection of 45 anomalous human spines which he has been several years in bringing together. Some of the specimens are unique, others are extremely rare. All are ligamentous preparations, which precludes the possibility of error in the number of vertebræ in reassembling the spines. The an-

[1] Memoirs of the Boston Society of Natural History, vol. v, No. 7.

nounced purpose of the paper is "to discuss what these spines teach concerning the significance of numerical variation of the vertebræ" and "to make the collection available to others."

Assuming that Rosenberg's theory of the forward migration of the ilium in ontogenetic development is true, Dr. Dwight seeks to discover if it explains satisfactorily numerical variation in the number of presacral vertebræ. He concludes that the "intercalation theory" or "the better one of an error of segmentation" does not exclude Rosenberg's. As irregularities occur in so many combinations in the several parts of the spine it is difficult to fix upon a starting point. Rosenberg and most biologists would compare the twentieth vertebræ of one spine with the twentieth of all others, but Dr. Dwight believes that if it can be shown that a certain vertebra has a distinct teleological value it is to be taken as a starting point. He therefore adopts Welcker's idea of a *vertebra fulcralis*. This is the one that has most to do with supporting the ilium, normally the twenty-fifth. Sometimes it is difficult to decide which is the *fulcralis*, but where everything is variable we cannot "exact absolute stability from the *fulcralis*."

If we regard the spine above the pelvis as an apparatus that develops as a whole for the performance of several functions, we can understand why a tendency exists for parts in the same relative position with reference to the *vertebra fulcralis* to develop in the same way. It is unlikely that there is a precise number of human vertebræ. Variations increase downward until in the region below the vertebræ supporting the ilium the number becomes very unstable. Dr. Dwight finds in this investigation further proof in support of his well-known belief that many of the morphological variations are to be accounted for on the ground of fortuitous variation about a mean rather than as oscillations between reversion and progression.

The collection is classified in five groups: (1) Normal number of presacrals, but with irregularities at the junction of the thorax and neck or at the junction of thorax and loins; (2) twenty-sixth is the *fulcralis*, but the twenty-fifth is not quite separated from it; (3) more than twenty-four presacrals; (4) imperfectly developed presacrals; (5) less than normal number of presacrals.

Among the remarkable specimens are two spines with two additional presacrals with the last one sacralized on one side; a case of fusion of axis and third; a spine with fused atlas and axis, suppressed cervical, an additional lumbar, and sacralized on one side; a spine with anterior arch of atlas wanting, cervical rib on one side reaching sternum, suppression of thoracic vertebra; one in which there is a cervical rib to manubrium on one side, with the next rib ending in place of normal second, with no contact between the cartilages, suppression of a thoracic vertebra.

In conclusion Dr. Dwight states a number of deductions that seem justified and lays stress upon the action of "a vital principle" as a determining cause of the variations described; for example, "variations which separately seem either reversive or progressive generally lose that appearance when the whole spine is considered." "After the occurrence of the original error in development there is a tendency for the spine to assume as nearly as possible its normal disposition and proportions. This, as do also concomitant variations and indeed all development, implies a vital principle."

This paper considers a difficult subject, is based upon prolonged research, involves biologic principles of the first importance, presents new material and arrives at suggestive conclusions. It is illustrated with numerous drawings and is accompanied by a selected bibliography of 23 titles.

Experimental Research into the Surgery of the Respiratory System. An Essay awarded the Nicholas Senn Prize by the American Medical Association for 1898, by GEORGE W. CRILE, A.M., M.D., Ph.D., Professor of Clinical Surgery, Medical Department, Western Reserve University; Surgeon to St. Alexis Hospital; Associate Surgeon to Lakeside Hospital, Cleveland. Second edition. Philadelphia: J. B. Lippincott Co. 1900.

We did not have the pleasure of seeing the first edition of this essay, which, the author states, was undertaken in view of the fact "that there are a number of phenomena attending operations and injuries of the thorax and respiratory tract which are not sufficiently well understood for ready application in surgery." It is the result of research work extending over two years.

The writer has taken up the following different subjects in experimental work: "On the Cause of the Phenomena Attending the Inhalation of Hot Air and Flame," "On the Effect of Filling the Chest with Fluid," "On the Effect of Prolonged Manipulation of the Brachial Plexus and the Nerves Supplying Some of the Muscles of Respiration," "On the Cause of Collapse or Death from Blows on the Lower Chest or Epigastrium," "On the Mechanism of Drowning," "On the Cause of Certain Symptoms Observed on Entering an Atmosphere of Increased Barometric Pressure," "On Foreign Bodies in the Pharynx and Esophagus," "On Foreign Bodies in the Trachea and Larynx," "Laryngotomy," "Tracheotomy," "Intubation," "On the Cause of Certain Phenomena Attending Considerable Traction on the Tongue."

The author has brought to his work a knowledge of the technique of experimental physiology and has endeavored to explain some of the obscure phenomena that occur in surgery of the respiratory system. It is an essay which will repay careful study and is very suggestive as to lines of research work. We trust that Dr. Crile will continue his work, which is an investigation of surgical phenomena by methods of research work used in a physiological laboratory.

Tirard's Medical Treatment. A Textbook of Medical Treatment of Diseases and Symptoms for the Use of Students and Practitioners of Medicine. By NESTOR TIRARD, M.D., F.R.C.P., Professor of Principles and Practice of Medicine, King's College, London. Adapted to the U. S. Pharmacopeia by E. QUIN THORNTON, M.D., of Jefferson Medical College, Philadelphia. In one octavo volume of 624 pages. Philadelphia and New York: Lea Brothers & Co. 1900.

The author is professor of the principles and practice of medicine in King's College, London. This volume may be regarded as a supplement to the usual textbooks on medicine, in which the section

on treatment which follows those on history, symptomatology, diagnosis and prognosis is apt to be somewhat curtailed by the exigencies of a necessarily limited space. The sequence of the chapters rests on an anatomical and physiological basis. Where formulæ are given they have been adapted to the U. S. Pharmacopeia. The volume is an octavo of 630 pages and is divided into 25 chapters. The work of the author and the presentation by the publishers have been well done. The book will be found a useful one by advanced students and by thoughtful practitioners of medicine.

The Prevention of Valvular Disease of the Heart. A Proposal to Check Rheumatic Endocarditis in its Early Stage and Thus Prevent the Development of Permanent Organic Disease of the Valves. By RICHARD CATON, M.D., F.R.C.P., Hon. Physician Liverpool Royal Infirmary, Emeritus Professor of Physiology, University College, Liverpool. With 6 illustrations. London: C. J. Clay & Sons. 1900.

In this little book Mr. Caton supports the old dictum that the best treatment for acute rheumatism is six weeks in bed, at least in those cases in which the endocardium is attacked. He wisely pleads for prolonged rest, in cases where the valves are involved, as the most important element of success, to which a flannel suit, a light diet, small blisters applied to the upper part of the thoracic wall and the administration of sodium or potassium iodide are contributing factors. He reports 86 cases showing the success of this method of treatment. To some, however, the carping critic might urge that the murmur which developed was dynamic and not organic. The early chapters in the book are devoted to the frequency and gravity of valvular disease. A short chapter on pathology is contributed by Dr. Abram.

Tropical Diseases. A Manual of the Diseases of Warm Climates. By PATRICK MANSON, C.M.G., M.D., LL.D., F.R.C.P. (Lond.). Revised and enlarged edition, with 114 illustrations and 2 colored plates. London, Paris, New York and Melbourne: Cassell & Co., Ltd. 1900.

The first impression of the first edition of this book appeared in April, 1898, and was reprinted three times. The present is a revised and enlarged edition. During the two and a half years elapsing between the first and second editions much attention has been given to tropical diseases and some important changes have taken place in the views obtaining in regard to some of them. Dr. Patrick Manson is an eminent and experienced authority on tropical diseases.

While making no pretension to being more than an introduction to the department of medicine of which it treats, this handy little manual of 684 pages of reduced octavo size will be found most convenient and reliable either for the student, the physician's library or the traveller. The illustrations are good and well selected and the general make-up excellent.

The Prevention and Cure of Obesity. By ARTHUR B. CARTER. Boston: The Rockwell & Churchill Press. 1901.

This small book of 15 pages on a very knotty question does well to confine itself largely to the author's personal experience, "who reduced his weight forty pounds in nine months." As a record of a single case, the book is of value and interest.

THE BOSTON
Medical and Surgical Journal

THURSDAY, FEBRUARY 7, 1901

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

ANNUAL REPORT OF HARVARD COLLEGE, 1899–1900.

THE annual report of Harvard College, meaning thereby of Harvard University, a copy of which for the academic year from September, 1899, to September, 1900, lies before us, is never a dull and may generally be found to be a suggestive document. The present report is no exception to this rule, although the portions relating strictly to the Medical Department are perhaps less important than on some previous occasions.

The average age of the entering Freshmen in the Academic Department has diminished slightly of late years, chiefly because there has been a decrease in the number of abnormally old persons admitted. Three-eighths of the Freshmen admitted in 1900 were nineteen years of age or more. The president considers it desirable, and in this those interested in the graduate schools or departments as well as in the college must concur, that the proportion of persons entering between seventeen and nineteen should largely increase. In his opinion, there is no good reason why nine-tenths of all the boys who mean to go to Harvard College should not be fully prepared for admission at eighteen years of age.

The dean points out that it is too early as yet to determine whether the new method of admission to Harvard College is more difficult than the old, or less difficult. The fact seems to be that increase in some directions is counterbalanced by diminution in others.

The dean of Harvard College and the dean of the Lawrence Scientific School, writing without any comparison of views, both complain of the fact that students are inclined to neglect their duties because of small ailments, which in after life would never be allowed to interfere with their daily work. It is stated that this tendency should be resisted by all the administrative officers and by public opinion among teachers and students alike, for it is a bad preparation for the strenuous work of after life.

The dean furnishes tables relating to various points in the working of the elective system. These tables, it is thought, confirm the results of previous inquiries in several important respects: "Thus, they prove that

under a wide elective system there will be no extreme specialization, and there will be a fair amount of judicious choice of correlated subjects. The general conclusion is that a boy of eighteen who has had a good training up to that age will ordinarily use the elective system wisely, and that the boy who has had an imperfect or poor training up to eighteen years is more likely to accomplish something worth while under an elective system than under any other. The group system is the right one for professional schools in which the future career of every student is assumed to be determined. When a youth has made up his mind to be a minister, a lawyer, or a mechanical engineer, there are, of course, certain studies to which he should by preference devote himself. A student in arts and sciences, if he knows what his future profession is to be, may wisely choose his studies with reference to that profession; but to that end free election is what he needs and not inflexible groups. A prudent student in arts and sciences who does not know what his profession is to be will choose his studies from among those which give him pleasure and in which he has capacity to excel, because it should be somewhere in these fields that he should find his future calling. For such young persons Shakspere's advice is the wisest possible — 'No profit grows where is no pleasure ta'en: — in brief, Sir, study what you most affect.'"

The president informs us that: "Observers of the newcomers to the Scientific School who have compared them with the newcomers to the college have formed the opinion that the average physique of the young men who enter the Scientific School is superior to that of those who enter the college. This observation is borne out by the fact that the Scientific School contributes a larger proportion of men to the various athletic teams and crews than the college. The cause of the phenomenon is not easy to discern. A corroborative fact appears in the absence records of the two departments: the demands made by the Scientific School upon its students under the group system are more severe than the demands made by Harvard College on its students under the free elective system; but there is no more sickness, or tendency to break down, observable among the students of the school than among the students of the college."

The neglect of the subject of physics by students, both of the college and the graduate school, still continues, and is considered one of the most curious phenomena in the university of today. In this respect, there is a great contrast between the department of physics and the department of chemistry, the resort to the chemical courses being much larger. In fact the chemical laboratories are full to overflowing. "The advanced courses in physics require a good knowledge of mathematics and this requirement may restrict the numbers choosing them; but the elementary courses do not require any advanced mathematics. The applications of physics in modern industries are certainly as extensive as the applications of chemistry, and the subject is even more many sided than chemistry. There is, as has been several times pointed out in these reports, a strong demand for competent teachers of physics, as well as for engineers who have received thorough training in heat, light and electricity. This limited resort to the courses in physics is not at all peculiar to Harvard University; it seems to be a widespread phenomenon. There are some indications that the number of students attending these courses is gradually increasing, but that increase ought to be large and rapid."

It is interesting, on the other hand, to note that: "The psychological laboratory furnished the demonstrations given in Professor Münsterberg's elementary course in psychology, a course chosen by three hundred and forty-six students, and also the experiments in Dr. MacDougall's course in experimental psychology; but its chief work was, as usual, original research carried on by advanced students and the instructors. Some of the subjects of investigation were complicated color illusions, the difference between memory for words, for perceived objects and for activities, the relations between memory and attention, some subconscious motives of judgment, the relations of rhythm and rhyme, symmetry in artistic composition and the mutual interference of several coinciding volitional impulses. Some work was also done in animal psychology, a new department of the laboratory which was established in 1898–1899. Two of the subjects studied were the symptoms of memory in the newt and the training of the crayfish in new habits.

"The number of students prepared to do original work in investigation is increasing. As the psychological seminary is also increasing, the congestion in the laboratory becomes more and more troublesome. The department of philosophy needs very much a new building, with ample room for laboratories, seminaries and library, and as remote as possible from the noises of the city."

A considerable portion of the president's report is devoted to the expedition of the Cuban teachers to Cambridge in the summer of 1900 and its results. The general conclusion is reached that the expedition fulfilled to a remarkable degree the enthusiastic expectation of good anticipated for it by its promoters. In regard to the physique of the visitors, it is stated as a conclusion from general observation and from measurements taken by Dr. Sargent, that the Cuban women compare more favorably with the American women than the Cuban men with the American men.

The system of medical visitation of students is reported as continuing to prove itself useful in a high degree. The short course of lectures given by the medical visitor at the opening of the current year on the physical evils to which the student may be exposed, and on the means of preventing injury to health by avoiding excess in eating, drinking, taking exercise, or working, or by eating or drinking too little, sleeping too little, and taking no exercise, was thronged.

The Medical School has a larger proportion of teachers to students than any other department of the university, if one excepts the Divinity School. This makes the instruction in the Medical School very costly, and the tendency of the new methods of instruction, introduced during the past year, will inevitably increase rather than diminish this cost. Our readers will remember that the chief characteristics of these new methods were a condensation of the basic subjects of the first two years — such as anatomy, physiology, chemistry, pathology — into half-year periods; the division of the classes into small sections, and the combination of practical with written examinations. It is certainly too early to definitely determine the results of this method. The dean of the Medical School reports that the results show the changes to be in the right direction. The sequence of studies is better than under the old method. The reports from most of the instructors are favorable. In clinical chemistry the system does not seem to have worked well. The department of anatomy is disposed to suspend judgment with regard to final conclusions. No practical readjustment of the studies of the third and fourth years has yet been accomplished; but the amount of sectional teaching is greatly increased, and practical examinations are combined with the written.

The accommodations of the present Medical School building are reported as totally inadequate to the demands of the lecturers and the regular teachers in the laboratories. The dean states that scientific investigations and research work by the teaching staff are almost at a standstill, all the available room being needed for the sole purpose of teaching students. More land has been secured, and the necessary buildings must and doubtless will be provided.

GONORRHEA FROM A MEDICO-LEGAL STANDPOINT.

THE series of articles on gonorrhea published in this week's JOURNAL, and previously read at a meeting of the Improvement Society, are well worthy of attention. They present the most advanced views on the subject in many of its relations. Perhaps they present as wide a study of the subject as could be presented in a single evening, but one of the most interesting points from which they may be regarded is the value of the portions of the subject which are left out. If we undertake to indicate some of the interesting omissions, it is not for the sake of undervaluing the papers, but for the sake of showing how wide a field for study still remains.

The gonococcus must some time be studied as to its relations outside of the human body. Has it a habitat in either the vegetable or the animal world, and is its distribution possible without direct human intervention? What is the clinical difference between the urethritis in which the gonococcus is found and in which it is absent? The recognition of the fact that a gonorrhea may reappear after very considerable time has done much to simplify some of the difficult questions as to its origin, but there are still many cases which we are unable to explain.

It has always been an interesting subject to study the eruption which is described by the French as an occasional accompaniment of gonorrhea. Such an eruption seems to be unknown in this country and no one has as yet tried to reconcile the difference in the observations there and here.

Cowper's glands are known as the seat of a series of abscesses resulting from gonorrhea, but they still present a subject for investigation. The recent observations of the pathologists in regard to the occasional pathological complications are of great interest, and might well have been discussed for the instruction of the Improvement Society. And, in the light of recent pathological studies, gonorrheal rheumatism is of even greater interest. In connection with rheumatism, rheumatoid iritis deserves mention, but perhaps the most serious interest is awakened in the consideration of the medico-legal relations of the gonococcus. On the statements made in these papers there can be no question that the search for the gonococcus as made by the ordinary practitioner can be of absolutely no value in a court of law. If there is any value in a medico-legal sense in the gonococcus it can come only from the testimony of an expert and must be put practically upon the same basis as the search for poisons. It is even a question whether the study of its entity is sufficiently far advanced to make the testimony of an expert fit for production in court. This coccus was first known by its morphology, then by the fact that it was contained within the pus cells, then by its behavior under methods of staining, and now we are told that it can be fully recognized only by its method of growth in certain selected culture media, and that it will not grow on ordinary culture media.

No germ yet studied holds quite the same relations to the human race as the gonococcus. Its recognition is not of so great value to the patient in regard to treatment as in regard to the etiology of the disease. The reputation of individuals and the future happiness of families depend upon our knowledge of that organism. To such questions as arise in connection with it, no reckless, uncertain or doubtful answer can be admitted.

It seems fairly well established that the gonococcus is the active agent in the existence of gonorrhea. One cannot then be sure of a contagious gonorrhea unless the gonococcus is identified. No one but an expert in bacteriology can be sure of the gonococcus. Even the expert in bacteriology cannot be sure of the identity of the gonococcus except from its growth on certain media. Surely these cultural peculiarities on artificial media are not alone sufficient to justify the expert in swearing away a reputation. The absolute value of these cultures needs to be tested by their action upon the human urethra under circum-

stances which render any infection of that urethra, either in the past or during the time necessary for observation impossible, before the opinion of the expert can be unreservedly accepted. One cannot be sure that such experimentally infected urethræ can ever be cured, so that the opportunities for such crucial tests must be very few. One cannot then be surprised to find such statements as that in J. Dixon Mann's volume, on "Forensic Medicine and Toxicology," published in 1893: "Vibert and Bordas believe that the distinction between gonorrhea and leucorrhea cannot be determined with absolute certainty by bacteriological examinations even of the most complete kind, and, therefore, that an expert is not justified in affirming the nature of a discharge on this ground. These views were accepted by the *Société de Médecine Légale de France*, before which body the statements were made. In the present state of bacteriology we are not in a position to say that the presence or absence of gonococci would justify a statement on oath either for or against specific infection."

A statement made some years ago in one of our courts must hold good today. The gonococcus is highly interesting and of the greatest importance from a scientific point of view, but its position is not so firmly established as to make it a proper subject for medico-legal consideration.

MEDICAL NOTES.

A Physician Fined for Being Late at Court. — A physician has recently been fined in Philadelphia for not appearing promptly at court in answer to a subpena. The reason for the delinquency was the serious illness of a patient, to whom the physician thought his first attention should be given. The judge is reported to have said that his first duty was to the court and that although the case was so serious, it was, nevertheless, better that a patient should die than that the Commonwealth should be treated with contempt. The fine was finally remitted.

Bubonic Plague in Wales. — It is officially reported that a mill worker at Cardiff is suffering with bubonic plague. Another mill hand is suspected of having the disease.

A Bold but not a Bad Step. — The *Lancet* has at length taken heart of grace to burst the cerements of long habit and conservatism, and having waited until the beginning of the new century, has finally with great boldness ventured to put titles at the head of its editorials.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, February 6, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 70, scarlatina 28, measles 38, typhoid fever 7.

Statistics from the Annual Report of the Cambridge, Mass., Board of Health. — The reported cases of diphtheria for the year 1900 show an increase of 423 over those recorded in 1899, or almost 50 per cent. The greatest increase was in Ward 2, where 215 more cases developed last year than during the year before. A noteworthy section of the report is that which says that there was a decrease of 61 cases in East Cambridge, which has always been regarded as the part of the city in which the spread of contagious disease is most likely to occur. The case death rate percentage was 7.78. This is regarded as a low fatality record considering the total number of cases. Eleven more cases of typhoid fever were reported in 1900 than in the year previous. The reported cases of measles show a decrease of 335 from those of 1899. The decrease was evident in every ward in the city. Eighteen more cases of scarlet fever were reported in 1900 than in the preceding year. The total number of deaths recorded was 1,547.

Physicians' Automobiles on Park Roads. — Chairman Stratton of the Boston Park Commission has sent the following note to certain physicians, who have petitioned that they might be allowed the privilege of using their automobiles at all hours on the park roads, when upon professional business: "After careful consideration the board has voted that it cannot grant the petition of yourself and other physicians to use automobiles in all park roads at any and all hours when upon professional business. We feel that it would not be in the public interest to suspend the rules for a particular class, even one so deserving of consideration as your profession. In the extremely rare cases where it would be a matter of life or death, and two or three minutes are of vital importance, I do not suppose that you would hesitate to infringe a park rule or that any one would call you to account for so doing."

The Care of Cases of Delirium Tremens and Suspected Insanity. — The question of the proper place to care for places of delirium tremens and suspected insanity is again under discussion. At a recent meeting of the Public Institutions Conference Dr. H. C. Baldwin, chairman of the Board of Trustees of the Insane Institutions Department, brought out the objections to the present plan of sending such cases to Deer Island. It was suggested that the City Hospital was the proper place for them. The trustees of the City Hospital are said to be opposed to the plan.

Inspection of Tenement Houses. — The Boston Board of Health has begun an inspection of the tenement houses, relative to overcrowding. The inspectors have received instructions to make an examination of all dwelling houses occupied by more than three families, and where they discover defective sanitary arrangements, to take such action as is necessary to make the rooms and surroundings clean and healthy. In order to prevent unsanitary overcrowding the board

has decided to enforce more strictly the law which demands at least 300 cubic feet of air for each individual.

BOSTON HEALTH STATISTICS. — The number of deaths reported to the Board of Health for the week ending February 2d was 243, as against 223 the corresponding week last year, showing an increase of 20 deaths, and making the death rate for the week 22.6. The deaths from consumption were 28, pneumonia 37, whooping cough none, heart disease 26, bronchitis 11, marasmus 1. There were 2 deaths from violent causes. The number of children who died under one year was 28, under five years 58, persons more than sixty years 63, deaths in public institutions 63.

QUARANTINE AT CHARLESTOWN NAVY YARD. — Owing to the prevalence of diphtheria in and about the Charlestown Navy Yard, the training ship *Wabash*, the Marine Barracks and the Naval Prison at the Navy Yard have been placed under quarantine, as a precautionary measure.

BURIALS WITHOUT COFFINS. — It is alleged that an old Jewish burial custom of burying bodies without coffins has been revived in Boston. The Board of Health has investigated the matter and has ruled that the practice be discontinued.

DIPHTHERIA AT THE NAVAL HOSPITAL, CHELSEA. — About 30 cases of mild diphtheria have developed at the Marine Hospital in Chelsea. There is no apprehension regarding an extended spread of the disease.

NEW YORK.

THE BELL ANTI-CHRISTIAN SCIENCE BILL. — On January 30th a hearing was given at Albany, by the Assembly Committee on Public Health, on the bill prepared under the auspices of the Medical Society of the County of New York and of the State Medical Society, and popularly known as the "Bell Anti-Christian Science Bill," which, in the form of an amendment to the Public Health Law of 1893, makes the following definition of the practice of medicine: "Any person shall be regarded as practising medicine, within the meaning of this act, who shall prescribe, direct, recommend, or advise, for the use of any other person, any remedy or agent whatsoever, whether with or without the use of any medicine, drug, instrument, or other appliance, for the treatment, relief or cure of any wound, fracture, or bodily injury, infirmity, physical or mental, or other defect or disease." The hearing was attended by a large number of Christian Scientists, several of whom spoke against the bill, and by a considerable number of the medical profession. Among those who made arguments in favor of its passage were Dr. Elsner, now president of the State Medical Society, Dr. A. Jacobi, of New York, Drs. Clark and How, of Buffalo, and Mr. Andrews, counsel for the Medical Society of the County of New York.

FALSE ANSWER IN INSURANCE APPLICATION. — In a suit brought in the Supreme Court in Orange County, to recover the amount of a policy in the Northwestern Life Assurance Company, the defence interposed was that a false answer was made by the insured in his application for insurance. It was claimed that the answer, to the effect that former applications of the insured had not been rejected, was false. Proof was given at the trial that the answers in the application were in the handwriting of the company's agent; that the deceased made a full statement of his previous rejections to the agent; that he was not informed of the character of the answers inserted in the application, and that the application was not read to him when he signed it. The Appellate Division in Brooklyn affirmed judgment rendered in favor of the plaintiff, holding that the evidence was sufficient to sustain a recovery, and that the plaintiff was not required in such an action to secure a reply in order to entitle him to give testimony showing that the answers had been erroneously written by the company's agent.

DR. MARY WALKER ON BURIAL IN SKIRTS. — When Dr. Mary Walker, who is at present a resident of Albany, read an account of the funeral of Murray Hall, the woman who for so many years was regarded as a man, she is reported to have indignantly said: "I think it an outrage that they buried that poor woman in skirts. If anybody tries to put skirts on me after I'm dead I'll haunt them."

SMALLPOX. — During the past week a considerable number of cases of smallpox have been found in an upper East-Side district inhabited almost exclusively by Italians, and on the night of February 1st the officials of the Health Department made a systematic visitation of this "Little Italy," as the district is known, with the result of discovering 7 additional cases and the body of a child who had died from the disease during the day. Had it not been for the protection afforded by a force of 300 policemen, who formed a cordon around the district, they would undoubtedly have suffered violence at the hands of the excited residents. In one barricaded apartment 3 children, all suffering from smallpox, were discovered under a bed. Other cases were found hidden in closets and cupboards and in one or two instances fathers took their sick children in their arms and fled with them over roofs of houses.

MURRAY H. HALL WAS A "LADY." — One of the richest contributions made in recent years to "crowner's quest" lore is to be found in the verdict rendered last week by the jury in the case of the Hall woman, who passed in the community for so many years as a man. It was in the following remarkable language: "Murray H. Hall came to his death from natural causes. He was a lady."

ANNUAL REPORT OF STATE BOARD OF HEALTH. — The annual report of the State Board of Health shows that in 1900 the total deaths in the State numbered 128,468, an excess of 6,647 over the mortality of 1899, and of 8,000 over the average of the past

five years. The influenza epidemic of the year was unusually severe, lasting six months, and probably adding 11,500 to the number of deaths. There were 14 deaths from smallpox, 10 of which occurred in New York City.

Sing Sing Prison Buildings Condemned. — On January 30th, the State Board of Health passed a resolution declaring the buildings of Sing Sing Prison unfit to be occupied by human beings and recommending that immediate steps be taken to remedy the existing conditions.

President and Vice President of Medical Society of State of New York. — On January 31st, Dr. Henry N. Elsner, of Syracuse, was elected president, and Dr. Louis N. Lanehart, of Hempstead, vice president of the Medical Society of the State of New York.

A Centenarian. — Isaac Landy, a native of Kiev, Russia, died on January 28th, at the reputed age of one hundred and five. He did not come to this country until he was ninety-four years old, when his son, living in New York, sent for him.

Miscellany.

THE LAST ILLNESS OF THE QUEEN.

We are enabled to publish the following authoritative account of the last illness of Queen Victoria:

The Queen's health for the past twelve months had been failing, with symptoms mainly of a dyspeptic kind, accompanied by impaired general nutrition, periods of insomnia, and later by occasional slight and transitory attacks of aphasia, the latter suggesting that the cerebral vessels had become damaged, although Her Majesty's general arterial system showed remarkably few signs of age. The constant brain work through a long life of royal responsibilities, and the imperial events, domestic sorrows, and anxieties which have crowded into later years, may no doubt be held in some measure to account for this discrepancy between the cerebral and general vessel nutrition. Both the thoracic and abdominal organs showed no sign of disease. The dyspepsia which tended to lower Her Majesty's originally robust constitution was especially marked during her last visit to Balmoral. It was there that the Queen first manifested distinct symptoms of brain fatigue and lost notably in weight. These symptoms continued at Windsor, where in November and December, 1900, slight aphasic symptoms were first observed, always of an ephemeral kind, and unattended by any motor paralysis.

Although it was judged best to continue the negotiations for Her Majesty's proposed visit to the Continent in the spring, it was distinctly recognized by her physicians and by those in closest personal attendance upon her that these arrangements were purely provisional, it being particularly desired not to discourage Her Majesty in regard to her own health by suggesting doubts as to the feasibility of the change abroad to which she had been looking forward.

The Queen suffered unusual fatigue from the journey to Osborne on December 18th, showing symptoms of nervous agitation and restlessness which lasted for two days. Her Majesty afterwards improved for a time, both in appetite and nerve tone, in response to more complete quietude than she had hitherto consented to observe.

A few days before the final illness transient but recurring symptoms of apathy and somnolence, with aphasic indications and increasing feebleness, gave great uneasiness to her physician.

On Wednesday, January 16th, the Queen showed symptoms of cerebral exhaustion. By an effort of will, however, Her Majesty would for a time, as it were, command her brain to work, and the visitor of a few minutes would fail to observe the signs of cerebral exhaustion.

On Thursday these symptoms were more marked, with considerable drowsiness, and a slight flattening was observed on the right side of the face. From this time the aphasia and facial paresis, although incomplete, were permanent.

On Friday the Queen was a little brighter, but on Saturday evening there was a relapse of the graver symptoms, which, with remissions, continued until the end. It is important to note that notwithstanding the great bodily weakness and cerebral exhaustion the heart's action was steadily maintained to the last, the pulse at times evincing increased tension, but being always regular and of normal frequency.

The temperature was normal throughout. In the last few hours of life, paresis of the pulmonary nerves set in, the heart beating steadily to the end.

Beyond the slight right facial flattening there was never any motor paralysis, and except for the occasional lapses mentioned, the mind cannot be said to have been clouded. Within a few minutes of death the Queen recognized the several members of her family. — *British Medical Journal.*

HYPNOTISM IN FRANCE.

According to the *British Medical Journal*, by a recent decision the *Cour de Cassation* — which is the High Court of Appeal in France — has finally settled a question which has been left open ever since, six or seven years ago, two provincial assize courts gave contradictory decisions upon the question whether the treatment of patients by hypnotism or so-called "magnetism" constituted a breach of the law which forbids the practice of medicine by those who do not possess proper qualifications. The French law is so precise that there was no great difficulty in coming to this conclusion, the only defence being that the treatment of patients by hypnotism did not constitute the practice of medicine; but this contention was promptly set aside, as it cannot be maintained nowadays that medical treatment is limited to the administration of drugs. The French law restricting the practice of medicine to properly qualified persons is founded upon the principle that for the welfare of society no one should be allowed to exercise such delicate and important functions as are implied in the treatment of disease unless he has passed through as complete a training as the existing state of science can afford in all those branches of learning bearing upon the structure, the functions and diseases of the human body, as well as upon the actions of remedies.

METEOROLOGICAL RECORD

For the week ending January 26th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Deaths reported 2,572; under five years of age 695; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 579, acute lung diseases 461, consumption 290, diphtheria and croup 107, diarrheal diseases 56, typhoid fever 36, scarlet fever 34, whooping cough 14, cerebrospinal meningitis 9, measles 7. There were 34 deaths reported from influenza.

From whooping cough New York 6, Pittsburg 3, Boston and Cambridge 2 each, Providence 1. From cerebrospinal meningitis Boston, Worcester and Somerville 2 each, Baltimore, Providence and Gloucester 1 each. From scarlet fever New York 22, Boston 8, Revere 2, Worcester and Salem 1 each. From typhoid fever New York 12, Boston and Pittsburg 8 each, Baltimore and Providence 2 each, Lowell, Springfield, Chicopee and Medford 1 each. From measles Boston 4, New York 2, Pittsburg 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,789,099, for the week ending January 12th, the death rate was 19.6. Deaths reported 4,442: acute diseases of the respiratory organs (London) 392, whooping cough 110, diphtheria 81, measles 66, diarrhea 56, fever 41, scarlet fever 35.

The death rates ranged from 12.8 in Huddersfield to 27.3 in Salford: Birmingham 21.4, Bradford 19.7, Brighton 16.7, Bristol 20.0, Cardiff 16.2, Derby 13.8, Halifax 13.7, Hull 18.4, Leeds 20.1, Liverpool 24.9, London 19.6, Manchester 22.8, Newcastle-on-Tyne 20.0, Norwich 21.5, Nottingham 22.7, Plymouth 18.6, Portsmouth 20.6, Sheffield 21.0, Sunderland 21.3, Swansea 19.9, West Ham 14.1.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING FEBRUARY 2, 1901.

W. A. McCLURG, medical inspector, commissioned a medical inspector, November 19, 1900.

H. O. SHIFFERT, assistant surgeon, ordered to the "Franklin."

E. J. GROW, assistant surgeon, detached from the "Culgoa" and ordered to the "Glacier," and also to duty at Olongapo, P. I.

J. COWAN, pharmacist, detached from the "Culgoa" and ordered to the "Glacier," and also to duty at the Naval Hospital, Cavite, P. I.

M. R. PIGOTT, passed assistant surgeon, died at Annapolis, Md., January 31, 1901.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING JANUARY 31, 1901.

MCINTOSH, W. P., surgeon. To proceed to Jeffersonville, Ga., for special temporary duty. January 30, 1901.

PERRY, T. B., surgeon. Granted leave of absence for thirty days from February 11th. January 30, 1901.

MCMULLEN, JOHN, assistant surgeon. Upon expiration of leave of absence to proceed to Wilmington, N. C., and assume temporary command of the service during the absence of Surgeon T. B. PERRY. January 30, 1901.

CORPUT, G. M., assistant surgeon. To proceed to Cleveland, O., and assume temporary command of the service during absence of Surgeon W. J. PETTUS. January 26, 1901.

BOARD CONVENED.

Board convened to meet at Washington, D. C., on Tuesday, February 5, 1901, for the physical examination of second Assistant Engineer R. F. HALPIN, Revenue Cutter Service. Detail for the Board: Surgeon PRESTON H. BAILHACHE, chairman; Surgeon G. T. VAUGHAN and Assistant Surgeon B. S. WARREN, recorder.

LECTURES ON THE NEUROSES AND PSYCHOSES OF SPIRIT AND DRUG DISEASES.

Dr. T. D. Crothers, of Hartford, Conn., will deliver a course of clinical lectures "On the Neuroses and Psychoses of Spirit and Drug Diseases," at the hall of the New York School of Clinical Medicine, 328 West 42d Street, New York City. The first lecture will be given February 18th, at 8 P. M. The profession is cordially invited to attend.

RECENT DEATHS.

THEODORE DE CLERMONT MILLER, M.D., of New York, died on January 28th, from pneumonia, at the age of fifty-nine. He was a native of Washington County, N. Y., and was graduated from Bellevue Hospital Medical College in 1866.

HOMER OCTAVIUS JEWETT, M.D., the oldest practising physician in Cortland County, N. Y., and one of the best known citizens in that section of the State, died from pneumonia at his home in the town of Cortland, on January 30th. He was born in Lebanon, N. Y., March 31, 1819, and had practised in Cortland since 1849.

STEPHEN CHANDLER GREGGS, M.D., formerly one of the leading practitioners of Brooklyn, N. Y., and highly esteemed as an obstetrician, met with a painful death at Nutley, N. J., on February 1st. Dr. Greggs had been helplessly paralyzed for some time, and, in the absence of his usual attendant, fell from an invalid chair into a grate fire and was fatally burned. He was a native of Pomfret, Conn., and eighty-one years old. He was graduated from Brown University and from the Medical Department of the University of the City of New York. He had practised in Brooklyn for forty-one years and retired about five years ago.

A CASE OF CESAREAN SECTION FOR COMPLETE PLACENTA PREVIA.[1]

BY C. H. HARE, M.D., BOSTON.

Gynecologist to the Boston Dispensary and to Out Patients at Carney and St. Elizabeth Hospitals; Visiting Gynecologist to the Woman's Charity Club Hospital.

On October 24, 1900, Dr. Francis D. Donoghue read a paper before this society on "The Treatment of Placenta Previa by Cesarean Section." The paper can be found in the *Boston Medical and Surgical Journal* of December 6, 1900. In that paper the varieties, frequency, diagnosis, treatment and literature bearing on this subject are so fully discussed that they will not be repeated in this communication.

For the benefit of present and future study any new method of treating this most fatal complication of pregnancy certainly ought to be reported. So far as known, Dr. Donoghue's case was the fourth and my own the fifth case of placenta previa to be treated by Cesarean section, and I therefore desire to place on record a case in which the mother died in eleven hours after the operation and a premature child of about seven and one-third months died thirteen days after delivery.

Mrs. 2,318 entered the Carney Hospital about 2 A. M. November 9, 1900. She was sent in by Dr. Wm. H. Boodro, to whom I am indebted for the following history: She was born in Norway, age twenty-seven years, mother of two children aged five and two years, but the character of those labors is not known. She had had no abortions. The last menstrual period began March 26th, making the expected date of delivery December 31st. Dr. Boodro was first called about 2 A. M. November 8th; she had been flowing at times for twenty-eight days, and had once called a doctor. For three or four days before entrance there had been a constant slight flow, which became alarming after coitus a few hours before he was called. He found some clots but no dilatation and no pains. He made the diagnosis of placenta previa, explained her condition and danger, and advised her going to the hospital at once, but was flatly refused by herself and husband, and he then refused any further care or responsibility of the case; but he was again called about 1 A. M. the next night, when he was told that she had been having labor pains for an hour or two, and had flowed "quarts," as herself and husband put it. Dr. Boodro's examination showed a patient almost pulseless; the bed soaked with blood; many clots in the bed and filling the vagina; the os dilating. He at once sent for the Carney Hospital ambulance; firmly packed the vagina, but blood soon leaked through the packing; gave three pints of salt solution by rectum, and strychnia and other stimulants under the skin.

On my arrival at the hospital she was still bleeding freely. The os admitted the finger tip, which felt placenta entirely covering the cervix. The patient's pulse was 140 and very poor quality. The child was living, and though from the story it was about one and two-thirds months premature it was yet easy to think of the possibility that the child might be a month older than reckoned.

The case was certainly bad to face, either for a vaginal or abdominal delivery. It seemed to me the risks lay between rapid dilatation, version, delivery, and immediate intra-uterine packing to control the continued hemorrhage from a cervix probably torn, but certainly stretched and tired, against the risks of a Cesarean section; a known high mortality to both mother and baby by the intrapelvic route against a hoped for lessened mortality by Cesarean section even though such hope in the absence of reported cases was based on theory. I was in a hospital with everything one could ask at my disposal for a quick Cesarean section; it was my judgment that the danger would be about equal to the mother by either route, but less for the child by the abdominal route, and I advised Cesarean section, to which the patient gave consent.

She was at once sent to the operating room. The abdomen was prepared while ether was being given. A girl baby weighing five and one-half pounds was delivered in one minute and four seconds after the first incision in the abdominal wall. The baby breathed after a moderate amount of effort to resuscitate. The greater part of a very large placenta was on the right and posterior side of the uterus, but a smaller segment was attached to the opposite side, thus entirely covering the os. A few minutes were allowed for the uterus to contract and loosen the placenta and membranes, after which they were easily removed. The uterus contracted well. It was closed with two layers of interrupted suture of chromicized catgut. There was no bleeding from the incision in the abdominal wall, uterine wall, or placental site. From entrance to the hospital salt solution was given at intervals under the breasts, by rectum, and various stimulants hypodermically. After the uterus was opened a nearly constant stream of hot salt solution was poured into and upon it until the abdomen was closed, and the abdominal cavity was left filled with it. Ether was not well borne. The radial pulse was barely countable and intermittent before the first incision and at times during the operation could not be counted. The patient was returned to her bed one-half hour after beginning the operation. There was never any more vaginal bleeding. Pulse improved slowly. Temperature rose to 102.2°, then dropped to 100°. She rallied enough to inquire about the baby, and to talk with her husband. She was especially apprehensive about death and talked much about dying. After a few hours she became quiet and drowsy, but delirious when roused, and died eleven hours after operation. The baby left the hospital when eight days old, but died of acute inanition, we are told, five days later.

In looking back upon this case one can hardly help saying that this woman in all probability sacrificed her own life by refusing to follow the advice of Dr. Boodro at the time of his first visit. There is every reason to expect that a strong, healthy woman, which she is reported to have been, could easily have gone through a Cesarean section after the loss of a moderate amount of blood, since she survived the collapse before willing to go to the hospital, the continued loss of blood until delivered, and the shock of the operation for so many hours.

After reading statistics and cases and hearing the reports of other cases of complete placenta previa, I am led to believe that in most cases Cesarean section is fully as safe for the mother as delivery by the older methods and that Cesarean section will save far more babies — in fact, there should be almost no mortality

[1] Read before the Suffolk District Medical Society, Section for Obstetrics and Diseases of Women, December 26, 1900.

with viable babies delivered by Cesarean section. For cases where the mother is already collapsed from loss of blood we have some very bad statistics to argue for some new method of delivery; and with suitable surroundings and assistants I believe in Cesarean section. Taking cases as they come, with the life of both mother and baby to be considered, I believe Cesarean section will save more lives than vaginal delivery.

For the benefit of statistics to argue for my belief in Cesarean section I should have adopted vaginal delivery and in case of need let the fatality be lost in the large number already reported, and have awaited a more favorable case for a newer method of treatment. Until more cases are reported judgment must certainly rest between statistics and theory. Your severest criticism upon my judgment in this case is invited.

THE WOOLLEN YARN TRUSS IN INFANTILE INGUINAL HERNIA.[1]

BY E. S. BOLAND, M.D., BOSTON.

IT may be thought absurd to talk about hernia in this section, but as obstetricians we meet the congenital or infantile form often, and as the trusted family physician one ought to keep up with what is best to do for it until the little patients are well or old enough for operative interference for cure.

Malgaigen's statistics give 1 case of inguinal hernia out of every 21 children under one year old, and Bertillon believes that the proportion among poor and neglected children is relatively greater. Of course, a large percentage will recover spontaneously with little or no treatment, if hygienic conditions are observed, but doubtless the cure will be hastened or assured if some retentive means is used. The average mother has but little faith in the expectant treatment, and unless you are prepared with some very definite and promising statement and apparatus, she will not be apt to carry out your general hygienic directions.

The truss may be only a placebo, but even placebos are sometimes a necessity under conditions as we find them. If you fail to do something for the trouble, she will soon go to some one who will, and she may drift into less considerate hands.

It is hardly necessary to speak even briefly of the etiology of this form of hernia, but I think that so much has always been said about congenital anatomical conditions predisposing thereto that the fact is almost lost sight of that it is very often due to preventible conditions following birth. In treating such hernias, these predisposing or aggravating causes must be counteracted as much as possible to ensure a cure. Crying from colic, gaseous distention from indigestion or unsuitable food, coughing, straining from constipation or phimoses, vomiting, and rough handling or improper position in holding a baby may induce it, and must be avoided by general hygiene.

Ochsner insists, in addition, on the horizontal position in bed for at least six weeks, with the foot of the crib elevated so as to keep the hernial sac emptied and so allow nature to obliterate the canal.

Excluding strangulated hernias, which in infancy are fortunately rare, and call, as in the adult, for prompt surgical treatment, the great majority of these hernias can be retained by simple apparatus, and the emptied sac collapsing is obliterated by adhesion of its walls, fat accumulation or what not. To secure this end, the worsted skein truss has much to recommend it in the first year, when the frame is small, thin in flesh and tender to mechanical pressure or irritation. It is easily made to measure at the bedside, and afterward can be reduplicated by the mother at a cost of a few cents, so as to have several changes at hand. It must be worn day and night, even during the bath, and only removed when wet or soiled.

It does not annoy the child, and its use ensures the hearty co-operation of the mother in carrying out the equally important corrective measures. Before applying it, be sure to exclude undescended testicle or encysted hydrocele of the cord. Difficulty of reduction ought to suggest these conditions rather than a hernia.

To ensure success the protrusion should be slowly and thoroughly replaced, and the truss adjusted so as to retain it and still not be tight enough to chafe or annoy the infant. Although so cheap and simple, some skill is needed in making and using this skein truss.

Measure with a tape line the distance around the child on the plane of the pelvic inlet, beginning with and coming back to the hernia, then carry the line down on the perineum and up and out in the glutofemoral crease and almost to where it would touch the girdle part. Mark this length on the woodwork of the door or window casing, and at each end of it drive in a three-inch nail half way to the head. Over these nails wind the worsted, previously rolled from the skeins as bought, just tight enough to keep from kinking, and use thirty to forty threads according to size and strength required. Remove the skein, tie in the two loose yarn ends, and in one end loop a foot of white tape, and the truss is ready.

Carry it around the child with the long end at the affected groin, pass this longer end through the other loop and draw the long end down under the corresponding thigh and out and up in the gluteofemoral crease and tie the tape to the girdle. The doll which will be passed around will be the best means of illustrating the application. The doubled and loosely twisted yarn is so elastic that it will keep up a constant hug that will take up any slack made by the motion of the child. To the medical, or rather the surgical mind of today, the brilliant results of aseptic operations for radical cure make any other way look like a makeshift. But to the timid and solicitous mother, the fear of the knife, and especially the possible removal from home of the infant for operation, renders the tentative use of the truss a necessity.

Its use must be coincident with general measures to reduce intra-abdominal pressure to ensure the best results. Though this home-made affair has been before the profession thirteen years (since Pye described it in 1887) it is not as well known even yet as it should be.

Dr. W. J. Taylor, who wrote the hernia article for Keating's Encyclopedia of Diseases of Children, said that he had used it but once, and in Dr. J. A. Ochsner's admirable paper, read last June at the American Medical Association, he does not even mention it at all.

[1] Read before the Suffolk District Medical Society, Section for Obstetrics and Diseases of Women, December 26, 1900.

It is useless to take your time in detailing my 4 successful cases, for they are all practically alike. All were boys, the trouble was recognized early, the protrusion returned without difficulty and retained by the skein truss under the watchful eye of the mother. In fact, one mother, a trained nurse, by the way, was so anxious to ensure a cure and avoid operation that, having moved out of my neighborhood, she continued the use of the truss on her boy until at five years he began to kick on his own account against wearing it longer. Usually a cure can be effected in a year or less, but the continued use of it causes but little inconvenience. In 2 cases it failed, the children being somewhat older and their mothers inattentive. In 1 case I failed to recognize an encysted hydrocele of the cord, and in spite of my failure to reduce it, tried the truss on it with no result. Another practitioner proved equally lacking in acumen, and also failed to recognize the true nature of the tumor and to relieve it. This case turned up at the Children's Hospital on Huntington Avenue, and was promptly recognized and operated on successfully. I mention this case to show the ease with which one can be mistaken in such cases.

Résumé. — (1) The use of some retentive apparatus will hasten and assure the natural tendency toward cure in infantile hernia; (2) the worsted yarn truss is easily made to measure at the bedside; it is cheap, comfortable and can be worn by frail or delicate infants, where the ordinary truss is useless or too irritating; (3) with this or any other truss vigilance and intelligence must counteract the underlying or associated causes of the hernia.

DISINFECTION WITHIN OR WITHOUT THE BODY IN DIPHTHERIA.[1]

BY M. A. VEEDER, M.D., LYONS, N. Y.

The effectual control of diphtheria in an individual or a community is a problem that is exceedingly complex. Really, there are at least three forms of disease that have been confounded under the name of diphtheria. It is only since bacteriological methods of study have come into use that these have been distinguished from each other with precision, they formerly having been regarded as modifications of the same disease, rather than as separate diseases. They are diphtheroid, characterized by the presence of staphylococci mostly; true diphtheria, characterized by the presence of the Klebs-Löffler bacillus; and septicemic sore throat, characterized as a rule by the presence of streptococci.

Although these diseases occur separately from each other, they are nevertheless often associated in a characteristic way. Diphtheroid predisposes to the onset of diphtheria, so that if a patient having the former is exposed to the infection of the latter, diphtheria begins at once without an incubation period. In like manner either diphtheroid or diphtheria may prepare the way for septicemic sore throat. Indeed, it is doubtful whether streptococcus infection can establish itself in the throat at all without some pre-existing disease, or lesion of the parts, just as erysipelas starts from some small scratch or puncture. Thus the septicemic form of sore throat, although very fatal, is not very contagious.

Diphtheroid is a harmless affection except as it predisposes to diphtheria, or septicemic sore throat, or both. Diphtheria in and of itself is dangerous, but is most dangerous if it becomes the channel through which septicemic infection gains access to the body.

As against the streptococcus infection, antitoxin is powerless, but the antistreptococcus serum may be used with good effect. It is a peculiarity of the streptococcus to locate itself in the exceedingly tough and foul-smelling membrane that is characteristic of these cases. Hence the application of strong disinfectant remedies accurately to this membrane, as, for example, painting it with pure carbolic acid, has appeared to be of service, this being a measure not to be recommended in ordinary diphtheria.

Erysipelas, puerperal fever and septicemic sore throat are all forms of streptococcus infection, closely related to each other. Indeed, all these diseases may originate each other, the liability so to do depending upon the location of the infection in or on parts of the body accessible to touch rather than upon differences in the nature of the infection itself. The physician attending cases of either of these kinds, for his own security and that of his patients, must apply the principles of surgical cleanliness accurately and completely. It may become necessary to go so far even as to abstain from seeing cases of ordinary diphtheria, lest they become septicemic through contact of the physician in attendance upon erysipelas, puerperal fever, or septicemic sore throat. During epidemic prevalence of diphtheria the occurrence of diseases of either of these classes may have a special significance, and should be carefully watched, with full understanding of the danger involved.

Furthermore, every surgeon knows that the danger of septicemia is very much increased if operations are undertaken in buildings where the plumbing is bad, and where there are untrapped drains. It is true that antiseptic dressings decrease the risk somewhat even under the most unfavorable surroundings, protecting the wounded surface more or less completely. But a sore throat cannot be protected every hour and minute as is done by such dressings, and if that throat be diphtheritic, the barriers against septicemic infection are as absolutely down as though there were an open wound. The traditional prejudice against foul drains and the like as a source of specially malignant diphtheria is not without warrant. Indeed, such receptacles and not the throat itself appear to be the natural habitat of infection of this class. If carried on the person it is by accident rather than as a part of the usual life history of the streptococcus infection.

The Klebs-Löffler bacillus, on the other hand, appears to find its natural habitat in the throat, it becoming more or less atypical when grown in culture media outside the body. Although irregular in form, and having its presence masked by that of other microorganisms, there is nothing to prevent its growth in the albuminous matter crusting the interior of drain pipes that are never cleaned or flushed, unless it be too low a temperature at times. But the dried sputum from a diphtheria patient kept at ordinary temperatures has been found capable of originating living colonies of the bacillus for six months. This being

[1] Read at the meeting of the Medical Society of the State of New York, January 29, 1901.

the fact, the Klebs-Löffler bacillus certainly could remain alive perhaps from year to year in underground drains, although leading a fluctuating and precarious existence. Such receptacles are especially liable to contamination through rinsings or expectoration from the mouths of persons having diphtheria, and thus also the infection may be renewed and kept alive, the persons living on the premises originating their own antitoxins and becoming immune. Where this has happened, quarantine and antitoxin, no matter how carefully applied with the aid of bacteriological tests, fail to eradicate the disease completely. The writer has encountered what appear to be beautiful illustrations of this in three or four large institutions.

In an emergency of this sort, where it is not possible to wait for improvement of drain pipes and plumbing, it is well to know that such fixtures when incapable of being flushed adequately can be sterilized by the aid of chlorine gas. In the presence of the septicemic form of sore throat especially this resource may be of the highest importance.

Nor is the diphtheroid form of sore throat unimportant. This form of throat trouble is much more common at all times than is generally supposed, not attracting attention, recovery being so rapid, unless the more serious diseases of the throat become prevalent, whereupon numerous cases of this sort are brought to the attention of the physician, and are commonly classed as diphtheria for reasons that will appear shortly.

As has already been intimated, diphtheroid predisposes both to diphtheria and to septicemic sore throat, shortening the incubation period to such an extent that the bacteriological test may show the throat clear from diphtheria one day and strongly infected the next. There being such increased susceptibility, a diphtheroid case may readily become diphtheria in the very act of examination unless adequate precautions are taken.

The fact that the physician's own throat is not red or sore is not proof that it is not infected, for infection often occurs without symptoms, particularly in adults when strongly exposed, and there is no stronger exposure than to receive the spray that comes from the mouth and nostrils of a child that is crying and coughing, as they often do, during an ordinary examination of the throat. The writer has met with very conclusive evidence that such particles of spray floating in the air are able to convey the Klebs-Löffler bacillus a distance of several yards. If the physician thus infected during an examination goes to another case without proper precaution, even though it be at an interval of several days, his own breath and the spray from his lips in the act of talking, if nothing more, may convert a case of harmless diphtheroid into severe diphtheria in an hour.

This is the danger also that militates against the use of the bacteriological test to determine whether quarantine shall be established or not. Such testing can be relied upon with confidence at the outset of quarantine only when it can be known with certainty there is no secondary source of infection such as that just described. In other words, unless physicians in attendance upon cases of diphtheria, or moving about in a community where there is diphtheria, have their own throats tested in order to see whether they themselves are clear of infection, and especially whether any precautions they may take are adequate, it is better to regard all cases of diphtheroid as diphtheria, provisionally, using the bacteriological examination mainly for the removal of quarantine rather than for its establishment. If these suggestions are followed out thoroughly there may be a surprise awaiting not a few members of the profession. The very anxiety that leads to seeing cases frequently and testing and examining them often may be a means of spreading the disease.

The routine that the writer has been led to adopt is to be provided with squares of antiseptic gauze and corrosive sublimate tablets. A square of such gauze may readily be held over the mouth and nostrils with the left hand, while the right hand is free to use the tongue depressor or swab. Both hands and face should be wet with the sublimate solution before and after the examination, and the gauze may be burned after being used. This, together with frequent spraying and cleansing of the mouth and throat and nostrils, and bacteriological testing, affords very complete security against either giving or receiving infection.

There are many precautions that will readily suggest themselves in regard to the care and disinfection of articles that have touched the mouth and lips, and on which infection may remain for extended periods in the form of dried saliva. Perhaps the worst of all such articles is an ordinary lead pencil, the use of which should be absolutely forbidden every diphtheria patient.

The infection of milk through the agency of some one having a diphtheritic throat coughing or sneezing while handling it seems to have occurred in a case or two that have come to the knowledge of the writer. Sterilization of milk by boiling is the proper method during diphtheria epidemics, and always.

As regards ridding the mouth and throat of the in fection, there are a few points that deserve more extended notice than can be given them on this occasion. Especially important is the behavior of the diphtheria bacillus where there are cavities in the teeth. In such cases the person thus infected becomes immune as if from antitoxin, but there is frequent recrudescence of sore throat trouble, more or less typical in its resemblance to ordinary diphtheria. Often there are red spots somewhere near the bad tooth, or exactly opposite it on the interior of the cheek. These come and go, and there may be evanescent traces of membrane on the tonsils at intervals of weeks or months. Bacteriological examination at times shows the presence of the bacillus and at times its absence. Sometimes it can be found by inserting the swab into the tooth cavity when not apparent elsewhere in the mouth. A very interesting case of this sort under the observation of the writer, after an exceedingly prolonged quarantine, infected another person through the intermediary of a lead pencil, showing that although the bacillus had been present and absent in a curious way, and the throat symptoms had varied fitfully, that nevertheless there was true diphtheria infection throughout a period of at least four months. In this case there was a deep cavity between two teeth and recovery was not perfect until the tooth itself was removed.

In these cases the bacillus appears to be nourished by fresh supplies of particles of food, such as meat and potato, lodging in the cavity, as in a culture tube at each meal. Thus the process is perennial, and the

infection does not die out as it does when the throat alone is infected. It would seem that sterilization of the tooth cavity by cauterization would reach the source of the trouble at once, but it does not, the few bacilli remaining elsewhere in the mouth apparently reinfecting the cavity. A better plan is to insert a pledget of cotton saturated with some disinfectant solution before and after meals. Even then in very bad cases it may be necessary to have the tooth extracted.

An observation of this sort is very suggestive as to the amount of care required to be of any material service in ridding the mouth and throat of diphtheria infection by methods of disinfection. The perfunctory use of sprays, swabs or gargles accomplishes so little, apparently, in shortening the time of quarantine that some physicians practically have come to rely on giving the antitoxin and waiting. But where the infection is harbored and kept alive in the manner that has just been described, neither the antitoxin nor waiting will ensure recovery within any reasonable length of time. Meanwhile the person may have infected unconsciously an entire neighborhood or town.

Very likely the bacillus when lodged in the spongy portions of the tonsils, or in some fold behind the palate, or in the nostrils, will die out gradually as the person becomes immune, but the process of its removal may be hastened and made more secure by constant sterilization of the parts as far as possible. Remedies for this purpose should not be irritating, so that they may be employed constantly at very frequent intervals, the growth of the bacillus and its diffusion through the mouth being very rapid Peroxide of hydrogen made alkaline by lime water, or by the addition of equal parts of Dobell's solution, is very good. Freshly made chlorine water with the addition of a little tincture of iron is highly efficient. A soft camel's hair toothbrush kept in a two-per-cent. solution of carbolic acid and used with a lather of castile soap is of great service, as is also dental floss drawn between the teeth. Such measures persisted in will clear up the most refractory case as determined by bacteriological examination, as a rule, in about a month, very few cases showing perfectly clear in as short a time as three weeks.

It has been the purpose of the present discussion to outline a few leading features, so that whatever measures of disinfection are adopted, whether within or without the body, they may be used with full knowledge of the dangers and difficulty and complexity of the subject of the control of diphtheria.

Clinical Department.

A CASE OF IDIOPATHIC DILATATION OF THE COLON.[1]

BY MAURICE H. RICHARDSON, M.D., BOSTON.

The following case will show, I think, that there is much to be learned about dilatations of the colon and the so-called phantom tumor. The patient presented in the first place symptoms so suggestive of chronic appendicitis that her surgeon removed the appendix (January 13, 1899). This operation — beneficial for a short time, through suggestion perhaps — was not permanently successful. The symptoms returned, and the smooth, symmetrical, tympanitic enlargement of the abdomen convinced Dr. Fitz that the lesion was an idiopathic dilatation of the colon. On April 5, 1899, I opened the abdomen between the umbilicus and the pubes, and found a great dilatation of the sigmoid flexure. The dilated bowel filled the lower abdomen, and caused the enlargement observed by Dr. Fitz. It was not, however, such an excessive dilatation as I had already described in a case published in the *Transactions of the American Surgical Association*, 1892 — a tumor of the sigmoid flexure practically filling the whole abdominal cavity, crowding or compressing all other viscera against the abdominal parietes and itself rotated and obstructed. It was rather a conspicuous enlargement of the flexure, which, thickened, distended and bulging, formed within the abdominal wall a tympanitic tumor easy of inspection and of palpation. I removed this coil and sewed the lower extremity of the descending colon to the beginning of the rectum, making a straight, cylindrical passage where had been the tortuous and distended sigmoid coil.

The patient was immediately relieved of her symptoms and of her tumor. It was not many months, however, before she began again to complain of her pain and discomfort. The abdomen became more and more prominent, until she presented all the physical appearances of an excessively dilated coil.

I had this patient under frequent observation. She was able to perform light household duties. She was never free from abdominal discomfort and pain. The bowels were very hard to move. The abdomen presented a symmetrical enlargement — a rounded tumor, almost spherical, with its greatest prominence below the umbilicus. The tumor was tympanitic without tenderness — resistant, tense. It could not be felt bimanually. Examination always gave me the impression that if the abdominal muscles could be relaxed, the tumor would disappear. Indeed in the early history of this case the tumor would, under anesthesia, disappear. At the three last operations, however, the outline persisted under ether, though as a whole the abdomen was perhaps not so prominent. The great thickening and distention of the coil made it a real tumor — one that could be made to disappear only by emptying it or by removing it. In other words, it had assumed characteristics of a real physical entity, rather than of the disappearing phantom of its early history. How much effect the contractions of the abdominal muscles had on the outlines of the tumor, I cannot say, but I believe that they had much influence. The phantom is formed by a dilated intestine under a spasmodic abdominal wall. The spasm of the abdominal muscle is doubtless secondary to the intestinal lesion, and dependent upon it. It is involuntary and absolutely beyond the patient's control. When the intestinal dilatation is moderate and distributed throughout a considerable portion of the colon, relaxation of the muscular spasm is followed by a flattening out of the dilated bowel and disappearance of the tumor. When, however, the dilatation is excessive and limited to a single coil or small area like the sigmoid flexure, and especially if the gas does not escape from the dilated coil, relaxation of the muscular contraction produces no change in the contour of the tumor. I believe that the phantoms are early and moderate dilatations of the colon, and that

[1] Read at the Boston Society for Medical Improvement, November 12, 1900.

such disappearing tumors will sooner or later become real ones, removable only by excision.

Mary K.'s history bears out this belief. At the exploratory laparotomy of April 7, 1900, a large, dilated and thickened coil presented itself in the lower abdomen. Though this portion of the bowel had surprisingly few adhesions, it was deemed best to do nothing more than to separate them and make the coil perfectly free. The operation was a complete failure. Another attempt was made on June 27, 1900. Before attacking the tumor, I made a thorough survey of it. At the line of suture of the first resection — which, it will be remembered, made a straight passage from the descending colon to the rectum — a new coil had appeared, around the central portion of which could be seen the scar of the suture line. Not only had a dilatation begun here, but it had bulged and spread until a new sigmoid flexure had appeared, and one so large that it filled pelvis and whole lower abdomen.

This extraordinary sequence suggests more questions than answers. Why should the intestine become dilated again at the same point as before? For the same reason that it was dilated in the first place? It would seem only common sense to say that it was and for the very same reason. In sigmoid flexure dilatations, for instance, the obstruction is in the first instance dependent upon the shape and size of the coil, by which it becomes overdistended and sagging, perhaps kinking partially its outlet, obstructing its circulation — in a word, undergoing mechanical changes secondary to causes within itself. Such an explanation, though a matter of theory, seems one of common sense. Why then should a straight cylindrical coil, without lax and redundant walls, leading straight to an unobstructed rectum, dispossessed of mesentery and the power of accumulating feces — why should such a coil become distended to the extraordinary length of fifteen inches, and to a diameter sufficient to fill the lower abdomen, and that in this brief period of one year?

The explanation of the dilated and hypertrophied coil lies in the existence of some kind of a chronic intestinal obstruction, the nature of which we do not as yet understand. I have seen recently a sigmoid flexure leading down into the pelvis, dilated and thickened to an excessive degree. The patient had no symptoms referable to her large intestine — I do not know even that she was constipated. The condition of the sigmoid flexure and of the colon was not unlike that here described in the case of Mary K., except that it was less in degree. The abdomen was opened for the removal of the uterus from an exsanguinated patient. The pelvic portion of the sigmoid flexure was so large that it interfered much with the operation. I had been so much interested in dilated colons that I made a careful examination of this one. The bowel was much enlarged and its walls had the excessive muscular hypertrophy seen in chronic intestinal obstructions. The colon itself was elongated and tortuous. No obstruction was found in the pelvis. There was no opportunity to get a history bearing upon this case, but I believe it will appear that this patient had been habitually constipated and that there had been excessive gas formation. Though the sharp bend in the rectum presents ordinarily no obstruction, yet in certain cases it seems to me it must have some retarding effect upon the intestinal flow, especially when there is also an enlarged and retroverted uterus. Once the sigmoid flexure becomes dilated it is easy to imagine those secondary changes dependent upon the sagging of an overloaded and heavy coil.

Once having failed in this case to remove the cause by extensive resections — whatever the cause may have been — is it justifiable again to remove the resulting dilated bowel? It was with extreme reluctance that the idea of resecting the presenting coil was considered. Dr. Williams suggested that we reduce the size of the coil by numerous transverse infoldings. This seemed a happy thought. Dr. Jones, Dr. Williams and myself each took a line of infolding, and in a very short time the convexity of the dilated coil was so reduced that its course was a moderate curve from the pelvic brim on the left to the rectum. This operation was, however, completely ineffectual. The tumor remained; the pain and the discomfort persisted; the disability and discouragement continued. We were, therefore, forced to another, and, I hope, final operation. The dilated bowel was again completely excised after its relations especially with the rectum and uterus had been accurately determined. The bend in the rectum was repeatedly examined for a possible obstruction at that level, but nothing abnormal was found. The uterus was large and heavy, pressing backward upon the rectum. This position of the fundus seemed a possible cause of obstruction, and it was therefore stitched to the abdominal wall. Besides the new coil, the whole large intestine was to a certain extent dilated. It crossed from right to left in large and loose folds. This enlargement did not seem to me pathological. Though it was suggested to make an anastomosis between the cecum and the descending colon, I did not see prospect of enough gain to justify the risks of this, in my experience, dangerous operation. The patient has made a steady but slow convalescence. The abdomen, though full, has lost entirely its tumor outlines.

What the outcome in this case will be can be only conjectured. The operation seems very severe for the lesion. Though in many cases palliation may suffice, occasionally the surgeon will be driven to heroic measures. My experience in a previous case of perfect recovery after resection made me perhaps too sanguine in the present one. The operations were not performed in the second case, however, until the patient had convinced everybody of the hopelessness of medical treatment.

February 11, 1901. Since leaving the Deaconess Hospital, this patient has been complaining constantly of severe abdominal pain. The distention of the abdomen has in a large measure recurred. The patient's general condition is good, but the local trouble is little, if at all, better than in the first place. The abdomen is full, firm and tympanitic. The enlargement seems caused by tense and distended intestinal coils. It seems hardly possible that the transverse and ascending colon can have become distended enough to cause her present condition, or that a third sigmoid flexure can have appeared.

SOCIETY FOR THE STUDY OF TUBERCULOSIS. — We learn from the *Philadelphia Medical Journal* that a society for the study of tuberculosis, which takes its name from Laennec, the discoverer of auscultation, has been organized in connection with Johns Hopkins Hospital, Baltimore.

PLACENTA PREVIA CENTRALIS: REPORT OF A CASE.[1]

BY JOHN W. DEWIS, M.D., BOSTON.

I WAS called about 5 A. M., October 26, 1900, to see Mrs. C., who was "flowing." The husband, who was the messenger, said his wife was bleeding "very much, very much," and pleaded that I come quickly. As he expressed it, the blood came "as though poured from a bucket." The place was only a little way from my office, and I was soon there. I found the woman almost *in extremis*, and immediately sent for Dr. Dearing and Dr. Kepler. Assistance from the family or friends could not be considered.

The patient was a well-developed, well-nourished Jewish woman — a regular Amazon in build — thirty-six years old. She had three children, all normal births, the youngest child being three years old. There had been no miscarriages, no irregularities of menstruation. She was supposed to be within a week or two of full term. There had been no hemorrhage throughout pregnancy, no untoward symptoms. This morning about 4 A. M., she awoke and found herself bleeding, but had no pain. The hemorrhage increased rapidly, but had ceased when I arrived, though there was evidence that she had lost a great deal of blood. The face was dusky, cold sweat stood on her brow, and the skin of limbs felt clammy. Pulse was 124, and very poor in quality. I listened for fetal heart, and thought I could hear it just below umbilicus. The patient had no heart lesions.

As soon as I could prepare, I made digital examination, and found os dilated to about the size of a fifty-cent piece, and filled with a bulging mass that felt like placental tissue. It was an extreme case, and, Cesarean section being considered impracticable, I concluded to dilate cervix and deliver as quickly as possible. While waiting for medical assistance, I prepared 2 quarts of normal salt solution, and gave about 6 ounces per rectum, then a hypodermic of strychnine sulphate, gr. $\frac{1}{15}$, combined with atropia sulphate, gr. $\frac{1}{50}$, followed by another of digitalis, gr. $\frac{1}{25}$, combined with cocaine muriate, gr. $\frac{1}{4}$. A few minutes later ether was administered by Dr. Kepler, and I turned and delivered a living child. The whole time occupied was about three-quarters of an hour from arrival at house. As hemorrhage had recommenced, I began to dilate cervix without waiting for anesthesia. The placenta seemed to cover the whole lower uterine segment. I went up with my right hand to left, between placenta and uterine wall, the border of placenta being about a finger's length up. I found feet near fundus — an O. D. A. or O. D. P. — and brought down right foot and a hand. During dilatation there was moderate hemorrhage, checked by advent of child's buttocks. In a few moments the head was delivered, and with it about two-thirds of placenta. A hemostat was placed on the cord, and the child, though much blanched, soon responded to external stimulation and artificial respiration. After remaining portion of placental tissue, which was on right side, and some membranes were removed from uterine cavity, I gave a hot douche of permanganate of potash, 1–3,000. The uterus contracted well, and there was no further hemorrhage.

The mother's condition now seemed better than before delivery; pulse about 130, but much improved in quality, due probably to administration of ether. I again gave, per rectum, salt solution combined with whiskey, which was retained. There had been only primary anesthesia, and no vomiting followed. About half an hour after delivery, the patient was given, by mouth, a teaspoonful and a half of fluid extract of ergot, and a little later, a hypodermic of strychnine, gr. $\frac{1}{30}$. Salt solution by hypodermoclysis was not thought advisable, as patient was comfortable, and seemed to be doing well. I remained with patient about two and one-half hours, watching pulse, uterus, and general appearance. During this time, pulse increased to about 135, and at times grew very weak, though never intermittent. She was given frequent sips of whiskey with water and a pinch of salt added. There was some thirst. At 9 A. M. the salt solution was repeated, per rectum, and a solution of strychnine, gr. $\frac{1}{30}$, given by mouth. Patient felt comfortable. I decided, however, to try salt solution subcutaneously, and went to my office for tablets, leaving patient in care of two intelligent women. I had only reached the house when the husband was after me, saying wife was "taken bad." I hastened back and found her pulseless and gasping, and in a few moments she was dead.

I was told that I had only gone from house when patient began to complain of pain in chest and stomach, and "bad feeling"; then suddenly catching at her breast, with a cry, she sat up in bed, and fell back senseless. There was no post-partum hemorrhage. The uterus contracted and remained so, as in any favorable case. The napkin, examined after death, was only moderately soiled, and there were no clots in uterus. Autopsy was not permitted, but I believe the sudden death due to embolism. The child died on the fourth day, but with proper care might have lived.

The point that stands out most clearly in the history of this case is, that there had been no hemorrhage, no warning of danger throughout pregnancy, and yet this proved a complete "placenta previa." Cesarean section might be advocated in such cases, but I believe nothing could have been gained by the operation in this instance, where the pelvis was large, and the demand for immediate interference was so urgent that scarcely any of the ordinary preparations for laparotomy could have been made. In the majority of such emergencies, however, Cesarean section would seem the choice, and the time cannot be far distant when it will be considered necessary for the general practitioner, who does obstetrical work, to be competent to do this operation.

[1] Read before the Suffolk District Medical Society, Section for Obstetrics and Diseases of Women, December 26, 1900.

A CASE OF COMPLETE PLACENTA PREVIA.[1]

BY FREDERICK COGGESHALL, M.D., BOSTON.

ON the night of November 18th, I was called some distance into the suburbs to see Mrs. S. The message simply said that she was in labor and having a hard time. I went expecting at the worst a forceps case, but took the precaution to take a nurse with me, as I knew nothing of the one I was told was on the case. I found a well-developed, well-nourished woman of thirty-three, who had been in labor with her sixth child for six hours, and had been flowing very freely from the beginning of the pains. At the onset of the labor

[1] Read before the Suffolk District Medical Society, Section for Obstetrics and Diseases of Women, December 26, 1900.

she had sent for an irregular practitioner who was engaged for the case. He had, after watching her for a time, given a very unfavorable prognosis, packed the vagina tightly with gauze and administered hypodermically something, as I was told, to stop the pains. As the family had been alarmed he had been dismissed, and they called me in. On my arrival the patient was blanched, with a feeble, rippling pulse which could not be easily counted or even felt. The bedding and mattress were soaked with blood, which was continuing to trickle out through the gauze. No contraction of the uterus had occurred for the last half hour which was severe enough to cause pain. The patient was only partially conscious, having just recovered, I was told, from a fainting fit. Pupils widely dilated. She seemed to me to be *in extremis* from loss of blood and if I waited to send for assistance it would evidently be too late. I therefore went ahead as best I could with the help of the two nurses. Before stopping to examine her I started the subcutaneous injection of decinormal salt solution. In preparing this I did not stop to sterilize the water. The delay was out of the question, and I took my chances. I used Dr. C. G. Cumston's solution for preparing salt solution, which was administered under both breasts and underneath the loose skin of the back at the same time by means of a three-way tube of a pattern contrived for me by Dr. Wm. H. Grant for the rapid administration of salt solution. The foot of the bed was raised. At the same time a tenth of a grain of strychine nitrate administered subcutaneously.

While the salt solution was being given I removed the packing and examined the patient. The os was dilated to something more than the size of a half dollar. The finger on being passed into the os did not encounter the membranes or the head, which could be felt externally well down to the pubis on the left, but came in contact with a soft, spongy, irregular surface completely covering the opening and through which the head could not be distinctly felt. This confirmed my first impression from the hemorrhage, that I had to deal with a case of placenta previa. By the time I had washed up and examined, the greater part of the salt solution had got in and I decided to empty the uterus as quickly as possible. The pulse had now considerably improved, though it was yet extremely feeble, about 150. The patient was still but half conscious. The side of the bed was now raised and she was placed across it. As the only chance of stopping the hemorrhage seemed to be to get the child out at once, I did a rapid manual dilatation, tearing the cervix deeply in three directions; I then swept the hand rapidly around, detaching the placenta, and tried to push it to one side; as it would not be gotten out of the way, I seized it on the inner side near the cord and dragged it out, grasped the child by the feet and did as rapid a podalic version as possible, and extracted the child without much regard to anything but the saving of time. The perineum was a complete wreck from previous labors, which facilitated my operation considerably. Much to my surprise, the child was not quite dead on delivery, but it was as much blanched as the mother. I felt compelled to leave it to the care of the untrained nurse, while with the other I devoted myself to the mother, who had again become pulseless and was entirely unconscious. The salt solution was repeated with some more injections of strychnine, and an enema of two ounces each of brandy and fluid extract of ergot with salt solution to make a quart was given.

As the patient had stopped breathing, although her heart could still be faintly heard, though not counted, artificial respiration, including the Laborde method, was applied. After a half hour's work her pulse began to be perceptible and she was evidently reviving. The uterus, which had received a very hot douche of 1–1,000 bichloride the instant it was empty and had then been packed with gauze on which I had emptied a two-ounce bottle of liquor ferri chloridi, had contracted down to extreme hardness almost at once, and the hemorrhage was all over within, I should say, two minutes after the child was out. The child, which had breathed well at first, had lived about half an hour, and was dead before I dared to turn to it. If I had had sufficient skilled assistance I believe it also might have been saved.

The mother remained in an extremely precarious condition for the next two days, but slowly recovered. Strange to say, there was no sepsis. The points at which the salt solution was injected were no sorer than is often the case after proper sterilization, which may be thought by some to be due to thorough local inunctions of Credé's ointment which were begun at once.

Medical Progress.

PROGRESS IN ORTHOPEDIC SURGERY.

BY E. H. BRADFORD, M.D., AND F. J. COTTON, M.D., BOSTON.

(Concluded from No. 6, p. 142.)

ABDOMEN OBSTIPUM.

HABS[29] reports a case of a six-months-old child with extreme contraction of the right rectus abdominis, resulting in extreme kyphosis. The muscle was extirpated and a complete cure ensued. The pathology was unknown; perhaps an intra-uterine myositis.

THE ANTERIOR SUPPORT OF THE FOOT.

Seitz,[30] after a thorough investigation, convinces himself of the existence of convex transverse metatarsal arch in 50% of all cases, the highest point being the head of the third metatarsal. The head of the first metatarsal bears more weight than that of the fifth. The tuberosity of the fifth metatarsal does not furnish a support for the weight of the body. The heads of the second and third metatarsal, contrary to a common opinion, do not furnish, as a rule, points of support for great weight, though they form segments in the arch. In 20% of the cases the head of the third metatarsal is found to have dropped, and in some cases the head of the second metatarsal also.

OBLIQUE OR UPRIGHT WRITING.

Schubert[31] has investigated a number of children in the schools in Nüremburg, to determine the effect on the position of the children of the different styles of writing. He finds that the inclination of the head to the side, rather than the upright and proper position

[29] Zeitschr. f. klin. Chir., 1899, S. 304.
[30] Zeitschr. f. orth. Chir., 1900, Bd. viii, S. 37.
[31] Ref. in the Zeitschr. f. orth. Chir., 1900, S. 152.

of the head, is more frequent in oblique than in the upright writing, the symmetrical position of the head being two and one-half times more frequent in the upright writing than in the oblique writing. In the position of the shoulders, only a third of the children held their shoulders in proper position in the oblique writing, while one-half held them properly in the upright writing. The position of the shoulders, however, was better in both groups than the position of the head. Obliquity of the head was not only more frequent, but was in a greater degree in the oblique writing than in the upright writing. The same is true of the forward bending. In upwright writing only 11% of the children were nearsighted; in the writing 15% and in the changing position 12%.

CONGENITAL ELEPHANTIASIS.

Froelich[32] reports a case of marked hypertrophy of the left leg, with a tumor of the dorsum of the foot and a second on the front of the lower leg. Elsewhere all the cellular tissue thickened and enlarged. A like condition on the other leg, but less marked. Deformities of the fingers and toes added to this. The tumor-like masses limited by deep constrictive bands. The author thinks the condition a lymphangiomatous one, due to the circular constrictions.

A like case of Reinbach's showed on microscopic examination a fibroid and lymphatic hypertrophy.

Jonan[33] reports 2 cases of hypertrophy of limb, and suggests a classification as needed; none suggested. The first case was a new-born infant, with hypertrophy of the left arm and a lymphangiomatous tumor of the left pectoral and axillary regions; the second a boy of three, with hypertrophy in volume and girths of both feet. No histological data.

Kirmisson[34] reports an interesting case of combination of congenital deformities of the supposed amniotic series. Amputation of one leg, a deep crease surrounding the other, syndactylism of the fingers of one hand, an annular constriction (slight) about one arm. A similar condition on one of the toes and a webbing between two other toes. He makes this case an argument to support his contention that syndactylism is of two classes: one where the condition is a persistence of the membrane which normally unites the fingers and toes in early uterine life, the other where (as here) the condition is evidently a definite pathological process, evidently primarily amniotic, where the adhesions are comparable to those resulting from burns.

FUNNEL CHEST.

Picqué and Colombaris[35] give most elaborate studies of a case of funnel chest, with a study of the cases recorded. Rarely rhachitic, usually congenital, in its beginning. The writers accept the theory of its being a *sternal* deformity due to softness of the sternum (possibly a delay in ossification) and to the influence of atmospheric pressure. In one of the cases here recorded the radiographic image showed a *marked* displacement of the heart to the left, a fact noted in the only autopsy on record and in other clinical cases. A good bibliography accompanies the article.

[33] Rev. d'orth., March 1, 1900, p. 77.
[35] Loc. cit., January, 1900, p. 61.
[34] Loc. cit., p. 67.
[35] Loc. cit., 1900, p. 157.

FAT EMBOLISM AFTER ORTHOPEDIC OPERATIONS.

Paye[36] reports 3 cases, in all of which in addition to embolism of the vessels there was a persistent thymus and large lymphatic glands. The author thinks this important; is inclined to consider the deaths, in spite of fat demonstrated in the vessels, to belong in the class of "thymus death," the deaths charged to "constitutio lymphatica." He adds a not very practical warning to avoid cases of this sort in regard to proposed operations.

THE TREATMENT OF TABETIC ATAXIA BY MEANS OF MOVEMENT.

Fraenkel[37] writes of the satisfactory results shown by his experience of what he terms compensatory movement treatment. The method requires considerable skill in the devising and use of the proper exercises varying with each case, according to the pathological conditions of each patient. The result of the treatment is said by the writer to be extremely satisfactory in causing improvement.

Ahrens writes of the value of apparatus as an aid in the treatment of tabetic arthropathies, and the unsatisfactory result obtained from operation, such as excision or incision.

CONTRACTION AND ANCHYLOSIS OF THE KNEE JOINT.

Blencke,[38] after a careful consideration of the subject, reports in favor of Helferich curved incision for the correction of the deformity in bony anchylosis of the knee. In the place of the wedge-shaped resection Ollier practised supracondyloid osteotomy.

TRAUMATIC SEPARATION OF THE EPIPHYSIS.

Wolf[39] describes the frequency of this affection, which since the introduction of the x-ray is more easily recognized than before. The treatment should consist in an accurate reposition of the fragments, the use of traction properly applied and the avoidance of too long a fixation of the joint.

Hutchinson and Barnard[40] advocate in traumatic separation of the lower femoral epiphysis that strong traction, progressive flexion and manual replacement of the epiphysis be combined simultaneously for reduction. Reduction accomplished, flexion is maintained with the heel on the buttock. Radiographs of cases before and after reduction seem to show the efficiency of the method. On the other hand, the statistics (of compound cases) treated by various older methods imply much worse results than obtain in this country today under present methods and may perhaps be misleading.

A New Medical Journal. — According to the *Medical News*, it is stated that subscriptions to the stock of a new medical journal, to be owned entirely by members of the profession and edited by Dr. Geo. M. Gould, have been unexpectedly great and now ensure the founding of the journal. It will be known as *American Medicine*, and it is expected that the first number will appear during March.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR OBSTETRICS AND DISEASES OF WOMEN.

W. H. GRANT, M.D., SECRETARY.

REGULAR meeting Wednesday, December 26, 1900, DR. HIGGINS in the chair.

DR. E. S. BOLAND read a paper entitled

THE WOOLLEN YARN TRUSS IN INFANTILE INGUINAL HERNIA.[1]

DR. WORCESTER: I have tried this truss and, although I never before understood how to apply it, I have had good results from its use. The rewinding of the skein to secure proper length and the tape fastenings evidently make it just right, easy of application and perfectly serviceable.

DR. COGGESHALL: I have never had but 1 case of the kind that I remember. My obstetrical practice is not very large, and I can only repeat what Dr. Worcester has said, that I tried this thing as I had seen it described and could not make it work. Obviously, as illustrated on that doll, I did not get it on right.

DR. CRAIG: I have used this truss on 2 cases, but I did not apply it as neatly as Dr. Boland has. In place of measuring it carefully as he suggests, which I can see is a much better way than that which I employed, I was very apt to measure off what I thought was right and carry it around the child, tying the end of the skein into the turn over the hip, which made it much more uncomfortable to the child than the tape would be. As to the results, 1 of the cases waited until I told them I was willing they should remove the truss and it was to all intents and purposes cured. The cases were seen while in general practice on the Cape and the second case was still wearing the truss when I left Provincetown. Aside from the difficulty of keeping it clean it is a most admirable means of retaining hernia. Unless the family surroundings are very good you will find it is apt to get soiled and become a nuisance in that way.

DR. HUBBARD: Last spring I was interested in the worsted truss treatment and followed some cases that came into the Infants' Hospital Out-Patient. I was able to get about 17 end results. Of these 6 were cures and 11 failures. Of course 17 cases are not enough to draw definite conclusions from, but there is at least one rather instructive and suggestive point. Of the 6 cases cured there was but 1 over two years old, or about 16%, and of the 11 failures 5, or 45%, were over two years old, so that the older the child the less likely the chance of cure.

As to the frequency of hernia in children, Kocher in an article reports a series of 70 new-born children in which the processus vaginalis was not closed in 34 cases. In another series of 100 children during the first three months of life it was found open in 37 cases, and in a third series of 188 children up to nine years old it was open in 41 cases.

DR. HIGGINS: Some years ago when I was doing work at the Children's Hospital, where there is a very large orthopedic out-patient clinic, including a good many cases of hernia, this worsted truss method was in very common use, especially on the young children. It was rarely applied to children over five years, and it was considered to be a very successful method. I know nothing about the statistics in regard to cure, but it was simply applied and kept on for a period of two years perhaps. If the mothers were careful and took good care of the children it usually resulted in cure; if not, and occasionally there was a case of large hernia where the truss could not control it, the children would be operated upon. Personally, when I was doing a little orthopedic practice at that time, I had 1 private case that came to me from New Hampshire. The patient wore a truss about a year and has been entirely well ever since.

DR. BOLAND: The truss does get wet and dirty, but the mother can have half a dozen and always have a clean, dry one. That is an objection, but it is an objection that holds good of any truss unless you have a covered steel spring with a hard-rubber pad and in young children under six months it is pretty hard to keep anything on. I think the truss has a limited range of usefulness among the younger children. My two failures were in children over two years old and in those where the activity brings more strain I think it will not do. In its own place I know it is of great help and it is a great comfort to the mothers. A skein of yarn costs twelve cents and will make four trusses.

DR. C. H. HARE reported a case of

CESAREAN SECTION FOR COMPLETE PLACENTA PREVIA.[2]

DR. FREDERICK COGGESHALL reported a case of

COMPLETE PLACENTA PREVIA.[3]

DR. WORCESTER: If I had heard from Dr. Hare that his case was successful I should not have come asking for the privilege of speaking upon the case, but I feel so keenly the danger of conservatism's triumph over the report of an unfavorable case that I want to say with all possible emphasis that I believe Dr. Hare did in this case exactly right. Of course he did what few surgeons now would do, but he did what I believe in a few years every surgeon will feel obliged to do. When the profession, after careful consideration, rises to a realization of the necessity of changing a time-honored treatment it means that the profession has appropriated truths recently discovered. There then follows a critical period when statistics are not trustworthy guides. Whether or no Cesarean section is the right treatment in cases of placenta previa is a question that does not yet depend upon statistics. And it may be that the operation for the next twenty times will be done only in such desperate cases that the mortality will be frightful. It may be that the men who undertake the operation will be as conscientious as was Dr. Hare that night when he thought of his duty to the mother and of his duty to the child rather than of the possible effect upon his statistics. In such cases the surgeon is justified in thinking of the effect upon the statistics only as regards the effect that statistics will have upon families who in the future shall be called to decide whether or no they will submit to radical surgical treatment. Never for any less worthy reason is the surgeon justified in declining to take the last chance, however radical be the step, even if the chance is one in a thousand.

In considering innovations we must never forget that

[1] See page 152 of the Journal.

[2] See page 151 of the Journal.

[3] See page 157 of the Journal.

what is theoretically right is right until disproved, and that proving comes only in fair trial. It is easy to lose patients in ways to which the profession and the community have become accustomed, and it is hard to lose patients in unaccustomed ways, after unaccustomed treatment, and cowardly men are apt to be overinfluenced by such considerations. It needs the quiet bravery of conviction, it needs the absolute disregard of personal reputation in order to bring into common use any new form of treatment. For instance, when the immediate surgical treatment of appendicitis first recognized to be theoretically right, it was much easier to let the patient die of general peritonitis, or inflammation of the bowels, or stoppage, or whatever the thing was called for ages, than it was to operate in proper time, and I remember in the discussions that we used to have years ago over the right or the wrong, just this question often arose, whether it would not be well to shirk an operation in a desperate case in order that statistics might not suffer, and I doubt not that many a life was sacrificed then by the timidity of surgeons who, thinking of their reputation or of the effect upon statistics, were unwilling to do what they knew was right. It is easy enough to stifle one's surgical conscience by blaming the ignorant family and friends, who of course are always ready to mistake the masked cowardice of the surgeon for a real interest in his patient. And it is also easy for self-satisfied conservatives to damn with faint praise or withering silence their braver comrades.

These remarks may seem irrelevant, but after hearing this admirable report of Dr. Hare's I feel we should recognize and applaud the surgeon's fidelity and skill. The case should not be reported as a case of the death of the infant, for under proper subsequent care the infant would doubtless have survived. At any rate the child would not have had so large a chance of life or lived so long had it been delivered in any other way. Cesarean section always gives the child the greatest possible chance. Instead of precarious passage through the parturient canal, the Cesarean child is gently lifted up into this world. And as for the mother, when we balance against the danger in even fairly normal labor to which the woman is subjected nervously and physically and the injuries she is liable to suffer, with their long evil sequence of ill health — when we balance against these dangers the slight dangers of a Cesarean section it is not a wild belief that womankind would take it easier. And certainly in labors that present unusual difficulties just as soon as the advantages of this operation are pointed out to the laity, the laity will jump ahead of the profession in demanding it. That change has already come about in the treatment of appendicitis. The families of not over-intelligence demand operative treatment for appendicitis, and will now discharge a timid physician who hesitates to give that treatment, and will themselves send for a surgeon, or will themselves apply for admission to a hospital, when only a few years ago, as I have just said, a deal of persuasion was necessary to obtain the family's consent. The laity often advances faster than the medical profession in the adoption of an important method of treatment, and the profession, it seems to me, often underrates the good sense of the laity, the good sense of the common people, the good sense of ignorant people; and many times an entirely unnecessary compromise is brought about between the physician's conscience and knowledge of what is right with what he wrongly supposes will be the natural objections on the part of the family to carrying out that absolutely right treatment. And the unnecessary compromise often results in disaster.

It seems to me a very auspicious thing at this last meeting in this old hall, and at this last meeting of the dying century, that we should have before us for consideration the report of this case, illustrating the application of advanced surgery in the treatment of a dilemma such as hitherto has frozen the courage out of obstetricians.

I congratulate Dr. Hare from the bottom of my heart. He did exactly the right thing, and he should have the applause of the whole profession. Had we known of this earlier how many mothers might have been saved!

DR. BOLAND: I have had very little experience with placenta previa — 1 case at term and 1 at six months. Both babies died and one of the women came near dying. One case I carried alone, and in the other I had another doctor help me. I am satisfied the chances of the baby are *nil* with a forcible delivery under these circumstances. It is usually premature if it comes, and if you wait till term and deliver rapidly its chances are not the best. In the future if I am unfortunate enough to get a case of that kind I shall call an operating gynecologist.

DR. COGGESHALL: I should like to say in regard to Dr. Hare's case that I should have done just what he did; the mother was so far gone she would probably have died anyhow, and the case proves nothing against the method. I must confess that the idea of Cesarean section did not strike me very favorably at first; this I fear was due to a Boston prejudice against anything that was new; but having thought it over, I feel that I should do that operation by preference wherever I had the facilities at hand, or time to obtain them. In my own case I did not entertain the idea because there was no time to send for proper assistance or instruments.

DR. DAVENPORT, of Providence: I have had very little experience with placenta previa. I have seen only 1 case and that in consultation. That was in the late stages and we turned and delivered. I have been very much interested in the treatment of these cases by Cesarean section and I am very sorry I did not hear Dr. Hare's paper.

DR. JOHN W. DEWIS read a paper on

PLACENTA PREVIA CENTRALIS: REPORT OF A CASE.[4]

DR. KEPLER: I hardly think I can add a single word to what has been said by Dr. Dewis. The doctor was kind enough to call me to help out, and it certainly was a frightful case. Everything had to be done with great rapidity. I felt at the time, and I feel now, that Dr. Dewis's work there was very rapid and the very best that could be done under the circumstances and that the patient owed her sudden taking off in nowise to anything that was done by the operator. As he says, the case shows evidences of embolism. I did not hear the other papers, but I would like to know if embolism is associated as a rule with placenta previa. We were taught in the medical school to look out for embolism, and just why we should have had embolism in this case with the

[4] See page 157 of the Journal.

uterus contracted down hard and occurring several hours afterwards is a question I would like to have a little light on. Evidently that seems the reasonable cause for the very sudden death.

DR. HIGGINS: I should think Dr. Dewis's case was probably one of those cases of sudden death in or after delivery which we unfortunately see or hear about once in a while. I have been present or have had my hand in 2 cases, 1 of which died with the suddenness of Dr. Dewis's case, and which was thought to be due to the dislodgment of a thrombus in one of the uterine sinuses, and the patient died with equal suddenness, and nothing would revive her. The second case was due to the same cause, and occurred about four days after delivery. I saw the case in consultation six or eight hours after she was delivered. It had been a case of adherent placenta, normal labor. The doctor had attempted to remove the placenta and it separated, and I was asked to see the case and to remove the rest of the placenta, which I did, using my fingers as a curette, as we have been taught to. That patient did perfectly well three or four days; she had no temperature, but a little abdominal distention and discomfort, and I was asked to see the case again in consultation with the same doctor because the husband was worried about her. Her bowels had not moved at the time, but she had absolutely no temperature and no peritonitis, but a little distention. While we waited the nurse gave her an enema which brought away a large movement, and I left in a half-hour, the patient apparently being in excellent condition. I stopped to see a patient on the way home, and when I got there I had already been telephoned for in great haste, saying that the patient had died. I saw the doctor and the husband afterwards, and learned that she simply turned over in bed and died very suddenly. The physician had left soon after I had, and there was no reason to account for it. Possibly the high enema caused the dislodgment of a thrombus, although it caused no pain at the time and the results were good.

In regard to Dr. Hare's case, I think we all are very much indebted to him for publishing the case. I myself know of several cases of fatal results after Cesarean section which have never been published, not occurring in my own practice, however. We have been taught to advise against the indiscriminate performance of Cesarean section, although we have recognized for some time it was a proper operation to do in certain cases of placenta previa, and it is very unfortunate that in starting out to do the operation we should meet with a death at once. Of course that will cool our ardor to a certain extent, and, as Dr. Worcester said, physicians are very easily criticised for losing patients under some new form of treatment or when they are attempting any innovation. I think the mortality from Cesarean section is rather larger than we are led to expect from the published reports of series of cases. Of course we have seen some very favorable statistics, but those cases were done not exactly on selected cases, but under favorable circumstances and on good cases, and the mortality is much larger under general circumstances and the less discriminating operator than the ordinary 2% to 5% which we are accustomed to hear about. I think packing for placenta previa, if efficiently done, is a very good placebo. It, however, makes considerable difference which way the packing is done. I do not think an efficient packing can be put in with a patient on her back. I think it must be in the Sims position with the perineum retracted, and I also think it makes considerable difference what material is used. Dry, sterilized gauze in my experience has been the most efficient packing. Wet gauze or a gauze containing glycerin acts very much like a wick, and will sometimes help to keep up the flow.

Since Dr. Donoghue reported his case two months ago I have seen 1 case of placenta previa. It was rather an interesting case, because we had just been discussing the subject, and I was at a loss to know whether to do a Cesarean section or not. I was asked to see the case about 6 o'clock one evening a month ago. She had been flowing a good deal all through the day. Pulse had gone to 120, and she was rather nervous and restless. I advised packing, and she was packed thoroughly and efficiently. That absolutely controlled the flow for the time being and I saw her again about five hours later. The packing was removed and it was only about half stained through. About half the gauze in the vagina was stained, and there was a moderate amount of dilatation, perhaps to the size of a ten-cent piece, so that packing had pretty well controlled the hemorrhage. However, she was repacked at the time, and about 4 o'clock in the morning that packing leaked very slightly and was changed again, and at 9 o'clock the packing was just beginning to leak the second time. The packing was entirely removed. There was dilatation of about 2 inches, and she was given a little ether and I delivered her with high forceps. It was a very easy case, and she made a good recovery and had practically no post-partum hemorrhage. The baby was premature, about seven months, and no fetal heart could be heard at any time, so that I think the baby was dead before we saw her.

In regard to the question of packing, I should like to say that I have never been able to see what the reason of it was, and should like to know whether it does any good, if the chairman can enlighten me. The difficulty, as I understand it, is with the hemorrhage you get when the placenta is detached. Now you simply postpone, it seems to me, the day of reckoning when you put in the packing; you may control the hemorrhage temporarily, but some time it must come, when the placenta is detached, and the placenta must be detached before the os can be dilated or the child can get out. I believe that the great mortality in this complication of labor is for the most part due to delay, and to failure to courageously face the difficulty. I did not mean to criticise the case the chairman reported, and the result justifies him, but most of the cases that have ended fatally of which I have been able to hear have been due to the doctors hesitating and sitting around waiting, like Micawber, "for something to turn up."

I have only treated 2 cases entirely on my own responsibility. In 1 case I was called early, the diagnosis was obvious at once and I emptied the uterus promptly. Both mother and child recovered without any difficulty, although the hemorrhage was for a short time appalling. The other case I have reported tonight. The 2 taken together seem to me to illustrate the different results of delay and prompt action. I feel that in another case wherever I dared to wait for proper instruments and assistance, I should do a Cesarean section.

Statistics as yet can have little value for us, and we must just judge of the two methods *a priori;* looked at from this point of view, Cesarean section presents the obvious advantage that the uterus is relieved of the child before the placenta is detached, and therefore the duration of serious hemorrhage is markedly diminished. My experience of Cesarean section for any purpose is very limited, but I doubt if the shock involved is any greater than that which accompanies operation by the old method.

Dr. F. G. Smith, of Somerville: This subject has interested me very much, as my first and only death in obstetric practice was due to placenta previa. This lady was eight months pregnant when I was called one noon and found that she had been flowing slightly. The mother of the lady was not at all alarmed; simply thought it was time I should be called and sent word. I made an examination, and found that the os had not dilated, and while I suspected placenta previa, I was not able to make a diagnosis. I had some gauze with me and packed the vagina, easily controlling the bleeding, and left the case, leaving word that I would call a little later. I had another call some distance away, and when I returned, about 3 o'clock in the afternoon, there was a message sent for me to call there immediately. When I reached the patient I found her *in extremis.* She had evidently lost a great amount of blood. Her pulse was hardly perceptible, her pupils were dilated, and she was almost wholly unconscious. I scrubbed up the best I could under the circumstances, not taking a great deal of time. Another physician had already been called and rendered valuable assistance. We gave a little ether. It was not necessary to give very much because of her condition. I removed the gauze packing, found the os had dilated, in which was a bulging placenta. I went in on the side, gradually separating it from the uterus, got hold of one of the feet and performed version. I think I was about three minutes in removing the contents of the uterus. She flowed dreadfully while I was doing this, but I got good contractions and gave normal salt solution by the rectum. I stayed there till about 8 o'clock in the evening. She seemed to be doing quite nicely, when suddenly the pulse stopped and she was dead. Whether this was a case of embolus, as Dr. Lewis suggests happened in his case, I do not know, but it occurred to me it might be that. She seemed to be doing quite well, but she died very suddenly.

Dr. Higgins: In my statement I did not intend to suggest packing as a means of dilatation or delivery, only simply as a temporary expedient. I think the fatal result in a great majority of cases of placenta previa that are delivered by the natural passage is due to the additional shock of immediate delivery, and the additional hemorrhage which is going on during delivery, together with the post-partum hemorrhage. The hemorrhage usually would not be serious during delivery were it not for the previous hemorrhage. I think this packing is a good temporary expedient while you are getting ready to do Cesarean section or giving the woman subcutaneous salt infusions to get her in better shape for the time being. I think you can pack the vagina so tightly as to control all hemorrhage a short time. Of course that stains through and leaks after a while. In this case I saw recently I neglected to say the pulse in the first five hours came down from 120 to about 80 after the packing, and she was in first-class shape to do anything at that time. This was not a case of complete placenta previa, although the hemorrhage led us to think at first it was. I have seen 6 cases altogether, most of them at the Lying-in Hospital. The second case I saw was one in which there was practically complete dilatation with complete placenta previa, and the hemorrhage had entirely stopped. The patient was under the charge of an externe in South Boston, and when I arrived there was no hemorrhage and dilatation was complete, and delivery was a very easy and simple thing. That is rather unusual, but still you might see it occasionally. The child in the case just spoken of was asphyxiated, as one would naturally expect. I think the fetal mortality is so large mainly because they are premature. I think it would be very interesting to compare the fetal mortality after placenta previa with the fetal mortality of ordinary premature infants, which is, as we all know, very large in itself.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Ninety-Fifth Annual Meeting, held in Albany, January 29, 30 and 31, 1901.

FIRST DAY.

Dr. A. M. Phelps, the president, delivered the

INAUGURAL ADDRESS.

He recommended that the way to securing membership in the society be made easier by having each county hereafter elect two delegates annually, each to serve for one year. He also thought it would be well to hold a semi-annual and exclusively scientific and social meeting in some other city than Albany.

REPORT OF THE COMMITTEE ON HYGIENE.

Dr. Henry R. Hopkins, of Buffalo, in presenting the report of this committee, spoke of the preliminary steps that had been taken towards securing State control of pulmonary tuberculosis, and reforms in tenement houses. The committee thought it desirable that gonorrhea and syphilis should be included in the list of diseases to be reported to the health authorities.

REPORT OF COMMITTEE ON LEGISLATION.

Dr. Frank Van Fleet, of New York, presented this report. It showed that out of the 268 medical bills presented to the last legislature, no bill had been allowed to become a law which was prejudicial to the society or to the medical profession.

Dr. Charles A. L. Reed, of Cincinnati, O., the president of the American Medical Association, being introduced to the society at this time, made a brief speech, the burden of which was that the trend of the present was towards unity and peace in the medical profession. He added significantly: "I am sure when you gather in our national council in St. Paul we shall be nearer an understanding on the unfortunate questions which have divided us for nearly two decades than we have been these many years."

THE PRIZE ESSAY.

The successful essayist this year was Dr. Lucien Howe, of Buffalo, the essay being entitled "On the

Management of the Interocular Base Line and the Size of the Meter Angle."

REPORT OF COMMITTEE ON STATE BOARD OF MEDICAL EXAMINERS.

DR. M. J. LEWI stated in this report that out of the 792 candidates for license, 143, or 18.05%, had been rejected. The regents had granted licenses to 107 physicians during the year.

RECENT PROGRESS IN THE TREATMENT OF ACUTE LOBAR PNEUMONIA.

DR. JAMES K. CROOK, of New York, read this paper. He said that no very striking innovations in our methods of treatment had been made recently, yet it was gratifying to note that while there were many minor differences of opinion, there was a commendable unanimity as to the underlying principles. In the present state of our knowledge not a single dose of medicine should be given simply because pneumonia was present; the indications should be watched for and met. The old-time poultice was being relegated to a well-deserved oblivion, and the use of ice bags and sponge baths was happily becoming almost universal. No more safe procedure than this would be found in the whole therapeutics of pneumonia. He favored the use of opiates, not as a routine measure, but carefully and discriminatingly to meet such definite indications as obstinate insomnia, intense nervous excitement or delirium. The same was true of alcohol. While it was usually indicated in chronic alcoholics and in old people, it was rarely required in others if the pulse rate kept below 110. Digitalis was losing favor, and caffeine was becoming more popular, while strychnine was generally admitted to be the most useful heart tonic in this disease. It should be noted that the specific plan of medication advocated by those who believe that pneumonia should be treated by combating the activity of the pneumococcus had not made much progress. There had been a surprising apathy among the French and Germans regarding the use of antipneumotoxin. Some progress had been made in our own country, but the chief obstacle was our inability to prepare an antitoxin of uniform and stable quality.

DR. ELISHA H. BRIDGES, of Ogdensburg, said that he could not accept the theory of the microbic origin of pneumonia. The one great essential in the treatment was securing to the patient an abundant supply of fresh air. Strychnine, morphine and alcohol were, in his opinion, the most useful remedies.

CONGENITAL DISLOCATION OF THE SHOULDER.

DR. DANIEL W. MARSTON, of New York, presented a communication on this subject. The majority of cases were dependent, he said, upon traumatism at birth, a fact that was emphasized in the frequent history of difficult labor. Our aim in treatment should be the reduction of the deformity and obtaining a useful joint. For patients under three years of age manual reduction was worthy of trial, but should this fail, operation should be resorted to.

THE RELATION OF APPENDICITIS TO DISEASES OF THE UTERINE APPENDAGES.

DR. A. L. BEAHAN, of Canandaigua, read a paper in which this relation was emphasized by the report of several cases. The association with menstruation of fever, tenderness over the appendix, constipation, flatulence, nervous irritability and exhaustion pointed very strongly to an appendicitis.

SMALL HOSPITALS AND THEIR ADMINISTRATION.

DR. LOUIS NOTT LANEHART, of Hempstead, gave his personal views on this topic, of much interest to many practitioners in the smaller towns.

THE NECESSITY OF GREATER CONSERVATISM IN THE USE OF VASODILATORS IN CERTAIN CASES OF CARDIOVASCULAR DISEASE.

DR. LOUIS FAUGÈRES BISHOP, of New York, was the author of this paper. He deplored the frequent routine use of the nitrites in doses not at all suited to the individual case, and insisted that in the successful use of these drugs each case must be a physiological study. If used in excess they cause dilatation of the heart and paralysis of inhibition.

WHAT IS RODENT ULCER?

DR. J. A. FORDYCE, of New York, with the aid of many fine photographs, pointed out clearly both the histological and the clinical features of rodent ulcer. He said that mistakes in diagnosis were not infrequent, and occurred for the most part in the late stages of this type of cutaneous cancer at a time when it was apt to lose its pearly-gray and thickened margin and appear only as an ulcer. While in the majority of cases it first appeared about the age of forty, it was by no means uncommon to see it much earlier. He had himself seen it as early as the twentieth year, and Hutchinson had seen it at the age of fourteen. Its first stage attracted little attention, and it was characterized by an excessively slow course and by very little new growth. The ulceration kept pace with or exceeded the newly formed tissue. Rodent ulcer when once well established exhibited a very strong tendency to recur after removal, and the lymph nodes did not always escape.

RECTOCOLONIC ENTEROLITHS AND CONCRETIONS.

DR. SAMUEL G. GANT, of New York, presented in this paper the results of a study of 53 cases. In 34 of these the stones had been situated in the rectum. They occurred more frequently in women and after the age of forty. Hair balls were also found, and oat stones in persons who had been in the habit of eating large quantities of oatmeal.

ESOPHORIA, OR LATENT SQUINT.

DR. FRANCIS VALK, of New York, contributed this paper. His views on the etiology of this condition were based on the muscular theory, associated with the fusion force of the eye. He believed that the straight muscles showed a certain power under stimulation of the fusion force, and that this power bore a certain relation to the action of the other muscles. The prism test he considered to be the only one that could be relied upon to indicate the true balance of power in these muscles, or the want of power, as an imbalance, as well as the probable muscles at fault. The histories of 16 cases were given briefly as examples of those showing latent convergent squint by the prism test. The operation employed consisted in a shortening of the external rectus by a "tuck" with a catgut suture, the latter being inserted while the muscle is held by the twin strabismus hooks de-

vised by himself. The reaction after the operation was very slight.

DEMONSTRATION OF THE OPHTHALMOPHACOMETER.

DR. LUCIEN HOWE, of Buffalo, demonstrated the action of this instrument, and presented simple formulæ relating to its use. The object of the instrument was to demonstrate the images formed by reflections from the surfaces of the cornea and crystalline lens.

CAN INTERSTITIAL KERATITIS BE PREVENTED IN THE OFFSPRING OF SYPHILITIC PARENTS?

DR. PETER A. CALLAN, of New York, replied to this query by saying that physicians could delay, but could not wholly prevent, the outbreak of interstitial keratitis in a certain number of cases. According to experience, the offspring of syphilitics show the inherited taint in only a small percentage of cases over five years of age.

RELATIONS BETWEEN CERTAIN DISEASES OF THE SKIN AND THE MENSTRUAL FUNCTION.

DR. L. DUNCAN BULKLEY was the author of this paper. He said that he had records of 42 cases in which this relation had been very evident. Acne was the most frequent cutaneous manifestation in this class. In a series of 510 cases of acne nearly one-third had shown a relation between the acne and menstruation. In 79 the acne had been aggravated by the approach of menstruation, and in 14 it had been worse after the menstrual epoch. There was a particular relation between acne of the chin and the menstrual function.

DR. A. JACOBI said that he had seen vicarious menstruation from varicose ulcers as well as from the ear and nose.

HYSTERICAL ANESTHESIA AND ANALGESIA.

DR. B. C. LOVELAND, of Syracuse, reported this case, which was one of hysteria major.

OPERATIONS FOR DEFORMITIES FOLLOWING POTT'S FRACTURE.

DR. W. O. PLIMPTON, of New York, reported 6 cases in which he had obtained a uniformly good result from division of the bone at the point of original fracture.

DEEP BREATHING AS A CURATIVE AND PREVENTIVE MEASURE.

DR. JOHN H. PRYOR, of Buffalo, pointed out in this paper the many therapeutic advantages of deep breathing, or, in other words, of thorough oxygenation. The effect of lung gymnastics on old exudates naturally received a large share of attention.

BELLADONNA VERSUS SCOPOLIA.

DR. REYNOLD W. WILCOX, of New York, pointed out the nearly identical composition of these two drugs.

INDICATIONS AND LIMITATIONS OF THE VAGINAL ROUTE OF ATTACK IN PELVIC DISEASES IN WOMEN.

DR. J. RIDDLE GOFFE, of New York, gave in this paper the latest accepted views of operating surgeons on this very important topic.

DISINFECTION WITHIN AND WITHOUT THE BODY IN DIPHTHERIA.[1]

DR. M. A. VEEDER, of Lyons, called attention to the advantages of using local germicides, and the danger of disseminating the disease during examinations or attempts at local treatment unless certain precautions were observed.

AFTER-THOUGHTS ON DIPHTHERIA.

DR. I. N. LOVE, of New York, spoke of the need for careful discrimination in drawing deductions concerning the results from the antitoxin treatment of diphtheria because of the progress that had been made in recent years in other methods of treatment. Much confusion had arisen from basing diagnosis and classification solely on the results of bacteriological examination.

THE TREATMENT OF PERSISTENT SUPRAPUBIC VESICAL FISTULA BY MEANS OF BOTTINI'S OPERATION.

DR. WILLY MEYER, of New York, reported cases illustrating this method of treatment.

THE PORRO-CESAREAN OPERATION.

DR. J. H. GLASS, of Utica, stated that the indications for this operation were: (1) Sepsis after protracted labor; (2) cancer; (3) large myomata; (4) atresia; (5) ovarian tumors; (6) hemorrhage, and (7) dystocia.

FATTY DEGENERATION OF THE HEART.

DR. THOMAS E. SATTERTHWAITE, of New York, read this paper, the object of which was to connect the three degrees of fatty degeneration, described by Bollinger in 1898, with three clinical stages. He was of the opinion that fatty degeneration of the heart is a common affection, attendant on and consecutive to various disorders. It was caused primarily by fevers, toxemias, disorders of nutrition and mechanical injuries. In the early stage the prognosis was best for complete recovery. Rest, tonics and nutrients were indicated in this stage. One should expect in the second or intermediate stage to so reduce the bulk of the fatty deposit that the muscular substance of the heart would recover enough of its normal tonicity to functionate physiologically. It was in this stage that carbonated baths and resistant exercises achieved their best results. In the final stage, when there was secondary implication of the viscera, the prognosis was necessarily unfavorable, though in rare instances the skilful use of modern therapeutic methods might result in recovery after attacks of ascites and cerebral effusion.

RECENT EXPERIENCES WITH ERYTHROMELALGIA.

DR. HENRY L. ELSNER, of Syracuse, in this paper spoke of combinations of erythromelalgia with Raynaud's disease and with syphilitic endarteritis obliterans, and stated his opinion that the disease depended more on arterial disease than on disorder of the nervous system.

RESULTS FOLLOWING THE CURE OF CHRONIC DEFECTS IN THE VESICAL FUNCTION.

DR. EUGENE FULLER, of New York, presented this paper. The object was to show that by appro-

[1] See page 153 of the Journal.

priate surgical measures it was possible in certain cases, in which the power of the bladder to empty itself had become impaired, to materially improve the condition. The most important of the factors leading to such crippling of the bladder were stricture, chronic contraction of the prostatic fibres around the vesical neck, senile prostatic hypertrophy, calculi and tumors. The direct causes for these conditions were vesical tenesmus, stagnation of urine and urinary infection. Long continued vesical tenesmus led to firm and unyielding bladder walls; stagnation caused stretching of those walls. The ureters and the pelves of the kidneys also showed the effect of chronic vesical stagnation. Thus, the ureteral orifices became very patulous, and the natural ureteral resistance to a vesical reflux being removed, the way was open for the development of a hydronephrosis. When the latter became extensive, the kidney soon became involved in the pathological process. Vesical infection added the inflammatory element to these processes, and the extension of this inflammation into the pelvis of the kidney was especially dangerous. It was most important that not only the disturbing factor be removed, but that rest of the bladder should be ensured by artificial drainage until the resulting lesions of the urinary tract had had time for repair.

A SIMPLE AND ACCURATE METHOD OF SUBSTITUTE INFANT FEEDING.

DR. HENRY DWIGHT CHAPIN, of New York, was the author of this paper. He said that in preparing the substitute food there were three important factors, namely, (1) Selection of good cow's milk; (2) suitable modification of the milk, and (3) the choice of a diluent. The same milkman's supply of milk varied little from day to day in the richness of the cream. Dilution of cow's milk with wheat or barley gruel, in which the starch had been digested, broke up the curds and so greatly aided digestion. This gruel could be prepared by boiling a heaping tablespoonful of flour with a pint of water, cooling and adding an aqueous solution of diastase. From 9 to 16 ounces of the top milk should be dipped off into a pitcher. Food for an infant should be made up of from one-eighth to one-third of 9 ounces of top milk, or of one-eighth to one-third of 16 ounces of top milk, the remainder consisting of digested gruel. One part of sugar should be added to 20 or 25 parts of food. Rich milk would require to be diluted more than poor milk. Each additional ounce removed from the milk bottles reduces the fat in the top milk from $\frac{1}{2}\%$ to 1%, thus cutting down the fat in the food $\frac{1}{8}\%$ to $\frac{1}{4}\%$, depending on the dilution.

ECTOPIC PREGNANCY; PRIMARY RUPTURE THE OPPORTUNE TIME FOR MAKING DIAGNOSIS.

DR. GEORGE MCNAUGHTON, of Brooklyn, considered in this paper the main points in diagnosis.

LEPROSY IN THE HAWAIIAN ISLANDS.

DR. CHARLES E. DAVIS, of Albany, gave an interesting account of leprosy as found in these islands.

AN X-RAY STUDY OF THE CAUSES OF DISABILITY FOLLOWING FRACTURES INVOLVING THE ELBOW JOINT.

DR. SAMUEL LLOYD, of New York, presented this communication. He said that so far as his experience had gone anchylosis at the elbow was true or bony. The function of the joint might be interfered with by the presence of callus, displaced bony fragments or by the head of the radius. If, under anesthesia, it were impossible to secure a satisfactory reduction of the displaced bones, the joint should be at once operated upon, just as one would do in a case of irreducible compound fracture. He favored putting up the arm in a flexed position, as that gave the most useful member in the event of anchylosis. Passive motion should be begun after three weeks.

DR. R. H. M. DAWBARN said that those who had not an x-ray apparatus at hand would derive much aid from the simple expedient of anesthetizing the patient and applying an Esmarch bandage. This, by markedly reducing the swelling, enabled the surgeon in most instances to arrive at a correct conclusion regarding the nature and extent of the injury.

(To be continued.)

Recent Literature.

Textbook of Histology, Including Microscopic Technique. By DR. PHILIP STÖHR, Professor of Anatomy at the University of Würzburg. Translated by DR. EMMA L. BILSTEIN. Edited by DR. ALFRED SCHAPER, Professor of Anatomy, University of Breslau. Pp. 432, with 301 text illustrations. Philadelphia: P. Blakiston's Son & Co. 1900.

Few textbooks on histology and microscopic anatomy have won such wide recognition in so short a time, as evidenced by the fact that it has passed through nine editions since 1887, and has been translated into Italian, French, Russian and English. The present volume represents the third American edition. When compared with the preceding American edition many points of superiority are noticeable. The portions dealing with technique have been carefully revised, a more precise terminology adopted and much new matter added. The more conservative may hesitate, however, to commend the phonetic spelling which the editor introduces, namely, "sulfuric," "sulfite," "pipet," "anilin," etc.

In the part on histology but few changes are apparent. The part on microscopic anatomy has not only been thoroughly revised but much additional matter has been incorporated, especially on the digestive organs. The author classifies these organs under I, Headgut, and II, Rumpgut; under the second division are the subdivisions: Foregut, Midgut and Hindgut. This classification is adopted without a word of explanation as to the meaning of these terms, and is therefore unintelligible to the student; not only is this true, but the classification is, in part, erroneous. Aside from this one objectionable feature there is nothing to detract from the excellence of this part of the book.

A distinctive feature of the American edition is a chapter by the editor on the uterus and placenta which is of great value to the medical student, and one which is not to be found in other textbooks. This and many other less important additions serve to bring together, in textbook form, the results of the latest researches in histology and microscopic anatomy.

One of the chief merits of the work, as stated in the editor's preface, is the brevity, precision and clearness of the descriptive text. The illustrations are for the most part original and possess a high degree of accuracy. Some, however, are copied from inaccurate originals. An example of such is Figure 287, in which the relation of the nerve endings to the auditory cells is incorrectly represented.

The translation is in general clear and concise; occasionally one finds a rendering which if given more freely would certainly be clearer. An instance in mind is the translation of the word *cellulifugalwärts* as "cellulifugalward."

The presswork is of the very highest grade. The illustrations are especially praiseworthy, while the typographical errors are few and of such a character that they are insignificant.

Orthopedic Surgery. By CHARLES BELL KEETLEY, F.R.C.S., Surgeon to the West London Hospital; Member of the British Orthopedic Society. London: Smith, Elder & Co. New York: C. P. Putnam & Sons.

This is a book of much interest to the orthopedic surgeon. The chapter on Coxa Vara is of value as the contribution of one of the early workers in the study of this lately found deformity. The book confines itself to that portion of orthopedic surgery exclusive of tubercular affections of the joint which in many places as deforming diseases ordinarily fall to the care of the orthopedic surgeon. The book is, therefore, of greater value to English than to American students, but it is of interest to all readers interested in the subject, as one of the best expositions of current English orthopedic surgery.

The chapter on Splastic Paraplegia advises myotomy and tenotomy and is, therefore, properly in advance of many neurological writers, but does not refer to tendon transference, which is now recommended by German surgeons. Trephining is mentioned as of possible use, but no cases are reported and the method remains as yet a suggestion.

The book is that of a student and of a man of ideas and experience, and is, therefore, a decided contribution to the art. The work is well but hardly handsomely illustrated, as is unfortunately the case with many English and American works on the subject.

In spelling the word "orthopaedic" the writer adopts English custom, although in the introductory lines of his work the word is correctly described as coming from the French *orthopédie*, derived from the Greek words *orthos* and *paidion*. Writers are justified in following sanctioned usage, but it is clear that reform is desirable in our cumbersome English spelling, and where authorities allow us, can we not be phonetic and also be right and simple?

The Use of the Röntgen Ray by the Medical Department of the United States Army in the War with Spain (1898). Prepared under the direction of SURGEON-GENERAL GEORGE M. STERNBERG, U. S. Army. By W. C. BORDEN, Captain and Assistant Surgeon, U. S. Army. Washington: Government Printing Office. 1900.

The title explains the general scope of this attractive volume of 98 pages with 38 full-page plates. A careful selection of cases has been made by the compiler; clinical histories are given in considerable detail, and only those have been chosen which illustrate important points in relation to the use of the x-ray. The chief value of the work lies in the x-ray photographs, which were evidently taken with much care and skill, and have been most admirably reproduced by the heliotype process. They have in no case been retouched to add to their clearness, a method to which recourse has too often been made of late. The work in this book also demonstrates that x-ray reproductions to be of value must be reproduced by the best processes on special paper. The typography is excellent, and the x-ray plates are among the very best we have had an opportunity to see.

A Textbook of Practical Medicine. By JAMES W. ANDERS, M.D., Ph.D., LL.D., Professor of Practice of Medicine, Medico-Chirurgical College, Philadelphia. Fourth edition, thoroughly revised. Illustrated. Philadelphia and London: W. B. Saunders & Co. 1900.

A yearly edition seems to be about the right standard unto which works on the practice of medicine should attain. This is the fourth edition of Dr. Anders's textbook. Advantage has been taken of the new edition for revision and rearrangement. He must be indeed a difficult practitioner or a difficult student of medicine who cannot find among all the works on theory or practice of medicine which have been placed on the market in recent years one or more which meet his requirements. It is evident that there are those who find their wants fulfilled by this textbook. It has many of the merits of its class and is not absolutely free from an occasional defect.

Saunders' Question Compends, No. 17. Essentials of Diagnosis, arranged in the form of Questions and Answers, prepared especially for Students of Medicine. By SOLOMON SOLIS-COHEN, M.D., and AUGUSTUS A. ESHNER, M.D. Illustrated. Second edition, revised and enlarged. Philadelphia: W. B. Saunders & Co. 1900.

This is the second edition of No. 17 of Saunders' Question Compends. There is evidently a large demand for such question compends. As we have more than once stated, we are not great advocates or admirers of these compressed self helps for "busy students and practitioners." This one is dedicated to the late Dr. Da Costa and is prepared by two of his former pupils, now professors in the Philadelphia Polyclinic. If one wants a compressed self-help question compend on the essentials of diagnosis this is a good one.

A Textbook of Pharmacology and Therapeutics, or the Action of Drugs in Health and Disease. For the Use of Students and Practitioners of Medicine. By ARTHUR R. CUSHNY, M.A., M.D. (Aberd.), Professor of Materia Medica and Therapeutics in the University of Michigan Medical Department, Ann Arbor. New (second) edition. In one octavo volume of 732 pages, with 47 engravings. Philadelphia and New York: Lea Brothers & Co. 1901.

There is not much to be said about the second edition of this work. It is but little more than a year since we welcomed the first edition, and sufficient time has not elapsed to require many changes. The book continues to represent modern medicine and today is the standard work in America on pharmacology and therapeutics.

THE BOSTON
Medical and Surgical Journal

THURSDAY, FEBRUARY 14, 1901

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS

COMPULSORY DISINFECTION IN TYPHOID FEVER.

THE discovery of the cause of an infectious disease should have as its principal result the prevention or limitation of that disease. This is the greatest benefit which such knowledge can bestow. In general our boards of health have been quick to take advantage of these advances in medical science. In typhoid fever, however, although our increased knowledge of the cause of the disease has led to much, it has led to less in the way of prophylaxis than should be the case.

Bacteriology has shown that the infectious material may be destroyed much more easily in some diseases than in others. For example, in diseases of which diphtheria is a type the infectious material is so disseminated from the patient that it is impossible to prevent persons and objects in close proximity from becoming infected. In such a disease isolation of the patient must be carried out, but if this is done thoroughly, there is little danger of the infection being carried to persons at a distance.

Typhoid fever is an illustration of a disease of a very different type. Here practically all the infectious material is in the urine and feces, which are received in a receptacle by the attendant. In that receptacle all the bacilli may be destroyed and almost all danger of infecting others easily removed by the addition of some suitable disinfectant. If this is not done, articles of food or the water supply may be infected, and the disease thus carried to persons at a distance. Nearly every case of typhoid fever that occurs has been infected from the excreta of a typhoid patient. To prevent typhoid, therefore, we have only to disinfect the excreta of every case.

These simple facts are understood by all practitioners. We mention them here only to emphasize their simplicity as well as their importance. It is hard to see how the control of any disease could be more completely in the hands of man. We should, therefore, expect that our boards of health would endeavor to insist that disinfection should be carried out in every case. In reality, however, we find that practically not much is done by health officials in this direction. Circulars have been issued, notably one by the Boston Board of Health, giving valuable instructions and inculcating good advice. A few physicians and most of the hospitals insist on disinfection, but this is not enough to have any appreciable effect in stamping out the disease. To this end, not merely must the gospel of disinfection be preached, but some means must be sought and, if possible, be found for enforcing its precepts.

As a result of our indifference to these precautions, typhoid, though most distinctly a preventable disease and though less prevalent than formerly, is constantly present in the community. It attacks chiefly those who are in the prime of life, and most needed for the support of the family. It takes away from the community and from public life many of those who can least be spared. Even in modern warfare it destroys more than the enemy's bullets.

The constant presence of typhoid in our midst is probably the cause of our comparative indifference to the disease. Cholera is spread in a similar way, and is probably not a more serious disease; yet the very name is sufficient to make the public shudder, and boards of health do their utmost to prevent it spreading from the cases that have occurred. What are the precautions which are taken in cholera? The same which should be taken in typhoid, a disease of similar origin and spread in a similar way, namely, a thorough disinfection of the excreta from the patient and of everything which may be contaminated by them. As a result of these measures, cholera is stamped out of every civilized community, and only occasionally gets a foothold through the neglect of proper precautions.

At the time of an epidemic of typhoid our health officials frequently display very great thoroughness and energy in tracing out the source of infection. The reports of these investigations, and of the following up of each clew, afford as interesting reading as a detective story. They fill us with admiration for the skill of the investigators, whose efforts, unfortunately, are seldom of more than a restricted benefit. On account of the long incubation period of typhoid the cutting off of the discovered source is merely locking one door of the barn after the horse is stolen. Direct this same energy toward securing disinfection in all cases and the disease will soon become extremely rare.

The remedy for this condition is to be found in legislation. The question of disinfection should no more be left to local boards of health in typhoid than it is in diphtheria and scarlet fever. There should be no local option in such matters. It is not sufficient that disinfection should be done in the city or town where we live. It is much more important that it should be done in the country places from which come our water and milk. Our Massachusetts law might be amended so as to require disinfection of the excreta in every case of typhoid

within the borders of the Commonwealth. The public statutes now require disinfection after diphtheria, smallpox, scarlet fever, or any other infectious or contagious disease dangerous to the public health. In compliance with this law our local boards of health carry out expensive formaldehyde disinfection of the infected rooms, although probably in those diseases the infection takes place in various ways. How much more important that disinfection should be done in typhoid, where every chance of infecting others may be removed by the destruction of all the bacilli!

The public statutes might require the local boards of health to send their agents or inspectors to every case of typhoid that is reported, to convince themselves that the dejecta are being properly disinfected. When necessary, disinfectants might be furnished free. If it is found that the directions of the board are not being complied with, they might have authority to remove the patient to a hospital where disinfection will be done.

The initiative for any steps toward securing disinfection in typhoid fever must come from the medical profession. The medical societies ought to take up this question. It should be agitated and brought before the legislature. Let us hope that very little of the twentieth century will have passed before measures will have been taken to stamp out the disease. May it no longer remain a reproach to our profession and to the intelligence of the age.

A PSYCHOPHYSICAL LABORATORY IN THE DEPARTMENT OF THE INTERIOR, WASHINGTON.

THE question of the establishment of a psychophysical laboratory at Washington has been under discussion for a considerable time. A Senate amendment to the Sundry Civil Bill for such a laboratory has recently been introduced, which provides $4,500 salary for the director and $16,500 for the expenses incidental to the collection of data and for necessary printing. Regarding the aims of the laboratory, it is stated that it is not to be in competition with other psychophysical laboratories in our country. Its purpose is to gather sociological, pathological or abnormal data, as found especially in children and in criminal, pauper and defective classes, and in hospitals. Besides these data it is desired to gather more special data with laboratory instruments of precision and to make such experiments or measurements as are generally considered of value by psychophysicists and anthropologists. While the field is necessarily a very large one, the purpose is to study in those parts of it which seem at the time to be productive of the most practical results.

It is to be hoped that such a laboratory may be established, and if established may confine itself closely to the line of work outlined above. That such work is needed there can be no question, and that it is eminently fitting that it should be supported and encouraged by the central government is equally evident. It is peculiarly true of investigations of the proposed character which this laboratory is to pursue that a very large number of data must be collected before conclusions of significance may be drawn. In the hands of a competent director it would no doubt be possible to bring about this result in a more complete way than has heretofore been done, and thereby provide knowledge of which we are certainly much in need. The loose, popular and often promiscuous talk of the last few years regarding degeneracy needs reconstruction and adjustment to the facts as soberly considered after years of patient investigation. If the suggested laboratory could, even in small measure, bring this about, its existence would be amply justified. In general, we are convinced that the intelligent collection of facts such as it is the design of this laboratory to accomplish in various lines of normal and abnormal anthropology is a work for which the time is ripe.

A PROPOSED MEMORIAL TO THE LATE DR. DA COSTA.

AN appeal is in circulation for funds for the establishment of a laboratory of clinical medicine in connection with the Hospital of the Jefferson Medical School in Philadelphia as a memorial to the late Dr. J. M. Da Costa. This appeal is the result of a resolution of the Board of Trustees of the Jefferson Medical School and Hospital to the following effect:

That for the purpose of commemorating the eminence of the late Professor J. M. Da Costa as a member of the faculty of this college, his notable career as a physician, and his distinguished services to humanity and to the advancement of medical science, a laboratory of clinical medicine, to be known as "The J. M. Da Costa Memorial Laboratory of Clinical Medicine," shall be established in connection with the Jefferson Hospital, and that the medical profession, the friends of Dr. Da Costa, and any others who may desire to contribute to the fund needed for the establishment of such laboratory, shall be given the opportunity of subscribing thereto.

It is proposed by those interested in this project to raise $50,000 for building such a laboratory, and $50,000 additional for its perpetual endowment. There is certainly no more worthy or fruitful purpose to which money could be devoted than this, if properly administered, and no representative of the medical profession in recent years more deserving of such a memorial than the late Dr. Da Costa. He was himself gentle, kindly, helpful, wise and learned, and a dispenser of all these eminently precious characteristics to others both in and outside of the profession of medicine through many years. He was known and appreciated both through his books and his personal teaching by great numbers of students and practitioners of medicine in many places. His skill, his judgment, his tact have profited many sick people whose diseases have thereby been healed, or whose burdens

have been rendered less hard to bear, and who cannot fail to hold the man and the physician in grateful remembrance.

This appeal reminds us that "he was for over thirty years a teacher of medicine, gave lustre to Philadelphia as a medical centre, and was known the world over as one of our ablest writers and most successful practitioners. It is fitting that a career so distinguished should be made memorable for all time by a laboratory in his chosen department. . . . For a generation Dr. Da Costa was the warm friend, the trusted adviser and in multitudes of cases the good angel at the bedside of the sick, often recalling to life and health our best-known citizens, or soothing their last hours. Many persons owe him a debt of gratitude which may well find expression in carrying on his work for the good of all future generations of poor and rich alike."

Those who make this appeal may justly remind the public that in Europe the sort of work which they propose to further is done in government laboratories for which large sums of money are appropriated. In our country "scientific medical progress is dependent upon the generous support of our enlightened and liberal fellow citizens."

MEDICAL NOTES.

"PLACE AUX DAMES." — The wrecking propensities of certain misguided women in the West have led in Chicago to a systematized attack on several drug stores. A daily contemporary remarks upon the event as follows: "According to a Chicago dispatch, half a dozen female followers of Dowie, the faith-cure healer, with the war cry that drugs are the agent of the devil, recently wrecked a number of drug stores on the west side of that city. Armed with pitchforks, umbrellas and canes, they succeeded in destroying property wherever they went. "Place aux dames" is a gallant motto, and a good one; but the place for these dames, apparently, is in the lunatic hospital. When lovely woman stoops to such folly as this, she will be likely to find that there comes a time when man's gallantry ceases to be a virtue."

PLAGUE IN INDIA. — According to the Bombay correspondent of the London *Daily Express*, plague prevails in every part of India, except the central provinces. There is said to be a weekly mortality of 2,500 in Bengal. In Bombay the deaths reach 94% of the cases. Ther is a lack of proper medical attendance.

A CASE OF SMALLPOX ON A CANADIAN PACIFIC TRAIN. — A man suffering from smallpox was recently found on a train of the Canadian Pacific Railroad. The car, which contained six other passengers, was detached from the train and placed in quarantine.

SMALLPOX AND PLAGUE AT MANILA. — Several cases of plague and smallpox have recently been discovered in Manila. The appearance of these diseases causes no alarm to the Health Board, as it is to a certain extent expected during the hot season.

SMALLPOX IN GLASGOW AND NORWICH. — There is a considerable epidemic of smallpox in Glasgow. On February 7th 33 new cases were reported. The disease has also appeared among the Thirteenth Hussars, stationed at Norwich.

PLAGUE IN CAPE TOWN. — It is reported that on February 8th 2 cases of bubonic plague had been officially diagnosticated at Cape Town.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, February 13, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 111, scarlatina 42, measles 29, typhoid fever 1.

INSPECTION OF FOOD AND DRUGS. — The following, from the *Weekly Bulletin of the State Board of Health*, presents the results of the examinations of food and drugs by the State Board of Health in the month of January, 1901: Percentage of adulteration, 29.03. The actual ratio of adulteration is very much less than this, since it is only suspicious articles of food to which the attention of the board is directed. Certain staple products, such as sugar, flour, and the various other cereal products, are very rarely adulterated, and require but little inspection. The work of the board is therefore mainly devoted to the inspection of such articles as it has found, by several years of experience, to be especially liable to adulteration. The ratio of samples of milk found to be below the standard was 34.9%, as compared with 40.9% for the preceding month, while the percentage of other articles of food found to be adulterated was 12.2. Ten complaints were entered in the courts during the month for violation of the laws relative to the inspection of food and drugs. Four of these complaints were for violation of the statutes relative to the sale of milk. Fines were imposed amounting to $110. The samples of drugs found to be adulterated were aqua destillata, acidum tannicum, calx chlorata, capsicum, extractum glycyrrhizæ, glycerinum, sodii phosphas, spiritus frumenti and tinctura iodi.

CITY HOSPITAL, QUINCY, MASS. — The trustees' report of the Quincy, Mass., City Hospital shows that the number of patients admitted to the hospital during the year 1900 was 230. Of this number 187 had been discharged, 28 had died and 15 now remain. Two nurses had been graduated during the year, and there are now 6 in the training class. The treasurer's report showed a deficiency for the year of $950. The total receipts for the year, including this amount, were $11,838.48, and the expenditures $11,780.76, leaving a balance of $57.72. The total endowment fund January 1, 1901, was $45,205.50. President William B. Rice offered to contribute half of the deficiency of last year provided the balance was raised in six days, and a committee was appointed to see if this could be accomplished.

Newton Hospital. — According to the treasurer's report of the Newton, Mass., Hospital, nearly all of the institution's indebtedness has been met and there is on hand at present $8,717. The earnings of the hospital for board, care and treatment of patients and earnings of the nurses outside during 1900 amounted to $31,527. The current expenses were $36,563.

Annual Meeting of Alumni Association of Boston City Hospital Graduates. — The Alumni Association of the Boston City Hospital Graduates held its annual meeting and dined at Young's Hotel, Wednesday, February 13th. The president, Dr. J. H. McCollom, was in the chair. Speeches were made by Drs. D. W. Cheever, J. G. Blake, Abner Post, George W. Gay, George B. Shattuck, J. L. Hildreth, H. W. Broughton, and Henry H. Sprague, Esq. Dr. W. E. Boardman was elected president, and Dr. W. A. Morris, vice president, for the ensuing year.

Smallpox in New Hampshire. — In the town of Harrisville, N. H., with 750 inhabitants, 15 cases of smallpox have appeared. Strict quarantine has been instituted over infected houses, and an isolation hospital is being prepared. The situation is somewhat serious. One case has also been discovered in the town of Milford.

Bill to Abolish Compulsory Vaccination. — The Committee on Public Health of the Massachusetts Legislature has been giving hearings on a proposed bill to repeal the law for compulsory vaccination.

Delinquency in Reporting Diphtheria. — Two physicians of Everett, Mass., have recently been fined in the court for failing to report a case of diphtheria in that city.

NEW YORK.

Typhoid Fever in Easthampton. — Prof. Olin H. Landreth, of the engineering school of Union College, recently visited Easthampton, Long Island, at the request of the State Board of Health, to investigate the causes of the prevalence of typhoid fever in the village. In his report he states that during and after the Spanish-American War there was constant intercourse between the people of Easthampton and the camp for returning troops which was established at Montauk Point, fifteen miles distant, where many working people were employed. The first marked results in the village were in the shape of numerous cases of tropical dysentery, during the autumn of 1898. One case of typhoid fever also occurred in August, 1898, the patient having been at the camp previously. During the following two years there were a considerable number of cases of typhoid, several of which occurred within 600 feet of the site of one of the hospitals where soldiers suffering from this disease were treated. The opinion is expressed that, whatever may have been the means by which the infection reached Easthampton, it became established there by soil implantation, and that it was disseminated either through the agency of percolation into the ground water, from which all the patients took part at least of their supply, or through the air, by the medium of dust blown by the winds. In conclusion, Professor Landreth says that unless vigorous sanitary measures are promptly taken there is danger of the disease developing, from the existing centres, into an epidemic during the coming season. Easthampton has long been a favorite summer resort for residents of New York, and has greatly increased in popularity since the extension of the railroad to the village a few years ago.

Building Fund of Mount Sinai Hospital. — At the annual meeting of the Mount Sinai Hospital, held January 26th, it was announced that the subscriptions to the building fund now amount to $1,190,830, leaving only $225,000 to be raised, and that work would be shortly commenced on the new buildings at Fifth Avenue and 100th Street. Among recent subscriptions are $125,000 for the children's pavilion, $75,000 for the dispensary building, $50,000 for the pathological building, and $20,000 for the equipment of the main operating room, all in memory of deceased relatives of the donors. Exclusive of gifts to the building fund, legacies and bequests to the amount of $14,771 and donations of $6,079 were received, and seven perpetual beds were dedicated during the year. The percentage of patients treated gratuitously was 80.60.

A Bust of the Late Horace Green, M.D. — At the meeting of February 7th, a bust of the late Dr. Horace Green, who died in 1866, was presented to the New York Academy of Medicine by members of his family. The presentation speech was made by Dr. D. B. St. John Roosa, who in the course of it took occasion to refer to the lack of recognition of the services of physicians to humanity in the Hall of Fame of the New York University. When, said he, the trustees were appointed to select names to be placed in the muster roll of men entitled to a niche in the Temple of Fame, not one member of the medical profession was considered worthy of a place either on that committee of 150 or in that hall.

President of the State Lunacy Commission. — At a meeting of the Neurological Society held February 5th, resolutions were adopted in regard to the qualifications required for the position of president of the State Lunacy Commission. They disapprove of any amendment of the insanity laws doing away with the clause providing that such officer shall have had at least five years' actual experience in the care and treatment of the insane.

A Heavy Verdict for Injuries. — On February 8th, a verdict for $28,000, said to be the largest ever given in Kings County against a railway company for personal injuries, was awarded in the Supreme Court, Brooklyn, to the wife of Dr. John M. Fowdrey. The suit was brought against the Brooklyn Heights Railroad Company, in one of whose cars Mrs. Fowdrey was severely injured in a collision.

Miscellany.

REPORT ON CONDITIONS AT BELLEVUE HOSPITAL, NEW YORK.

A COMMITTEE of five of the Medical Board of Bellevue Hospital, appointed for the purpose, has just made to Commissioner of Charities Keller a full report on the condition and needs of the hospital. The committee consisted of Drs. George B. Fowler, W. M. Polk, J. W. Brannan, A. Alexander Smith and Alexander Lambert. During the year 1900 24,300 patients were admitted, of whom no less than 11,370 were ambulance cases. The other hospitals in the city delivered in their ambulances to Bellevue 6,754 patients, of whom 107 died within twenty-four hours. This class of cases naturally affects materially the death rate, but the report says: "We cannot escape this burden so long as they (the other hospitals) are authorized by law to impose it upon us." Then follows a tabulated statement of the latest reported annual death rate in St. Luke's, the German, Presbyterian, Roosevelt, Mt. Sinai and New York Hospitals, as compared with that at Bellevue. "It is seen that, combined," the report comments, "they provide for a total of about 21,998 patients annually, with an average mortality of 9.44%; whereas this hospital provides for about 24,300 patients annually, with a mortality of 7.08%." The reception accommodation is entirely inadequate for the present needs of the hospital, and a number of suggestions are made for its improvement. The insane pavilion is carefully considered and the recommendation made by the Committee of Inspection is renewed, namely, that the patients sent to the pavilion should be placed under the charge of a competent salaried physician. There should also be an assistant resident physician, so that there should always be a well qualified medical man in attendance. The nursing service of the male ward of the pavilion should be in the charge of a carefully selected supervising graduate nurse, assisted by trained attendants. In the opinion of the committee, male pupil nurses are not fitted for the care of the insane.

Wards 32 and 34, known as the alcoholic wards, are the only ones in the hospital in which certain forms of epilepsy, hysteria, and even surgical mania, can be treated, and are greatly overcrowded, and the committee recommends that the members of the visiting staff exercise closer supervision of these wards than heretofore; also that the house physician and senior be assigned to duty in these wards, rather than a junior, as has sometimes been the case. While several of the pavilions standing on the grounds are commended, those recently completed, such as the ones for erysipelas and tuberculosis, are criticised on account of serious errors in design and construction. While the building now used for lying-in cases can only be condemned in every particular, plans are in preparation, it is stated, for converting the building on the hospital grounds formerly used as a medical college into a suitable place for such cases. As to the dispensary department the report says: "At the present time there is no direct supervision of any kind. Those left in charge are unfit to be in such a position, and there is a general laxity of discipline and observance of all rules that makes it a jumble of good and bad service. It can best be described as being in a state of vicious decay, and only the most radical measures can make it anything but a discredit to the institution."

Some fault is found with the feeding of the patients in the wards, particularly in the stages of convalescence, and it is suggested that a special committee be appointed with a view to placing the dietary as nearly as possible upon the same plane as was adopted in 1890. Outside the insane and alcoholic pavilions, where, as mentioned, pupil nurses are not approved of, the nursing service is regarded as satisfactory. In order to facilitate the work of the male nurses it is suggested that an assistant superintendent should be provided for each medical and surgical division. The report concludes in the following language: "We are of opinion that the rules and regulations of the hospital are correct upon the whole, that the various divisions and subdivisions of the force which is concerned in its conduct are, as far as circumstances permitted, organized upon correct lines. A division of authority has, however, existed, which has been responsible for the defective execution of the laws under which the hospital was supposed to live. This, as was stated to the commission some time ago, can be obviated by a head which places itself in contact with these various subdivisions and exercises immediate and vigorous control on all. This, we are glad to say, the commission has accomplished by installing Dr. Stewart. But permanent improvement is rendered difficult, and some of us believe impossible, in the face of the inefficiency of the paid employés, as a class, and the wretched accommodations furnished so large a portion of the staff, doctors and employés alike. Correct this and raise the per capita allowance of this hospital to a figure approximating that which obtains in like institutions in this city, and the crying evils will be permanently eradicated. Otherwise the outcome of this effort at improvement will end as the many which have preceded it. Decent service requires fair pay and decent accommodations. To which end we earnestly recommend that the main hospital building be replaced at once by a modern and more commodious structure, and the per capita allowance for conducting it increased to a figure approximating that under which other hospitals live."

WHAT IS BRANDY?

IN a case recently tried in Dublin before the Lord Chief Justice and a special jury in which the merits of cognac was under discussion, one of the witnesses is reported to have said that such a thing as cognac made from cognac grapes exclusively did not exist on the market. Two prominent firms, makers of brandy, have protested in a letter to the *Medical Press* that the statements made were false, and also incidentally that Cognac is a town, and not a vineyard. Commenting on the general question the *Medical Press* says:

"We recently discussed the question, 'What is Whiskey?' and events have occurred in the law courts during the past few days which render it necessary in the public interest to do the same for brandy. According to Dr. Murray, of dictionary fame, the original form of the word 'brande-wine' is a Dutch word, *brandewijun* — 'burnt' wine, — in familiar use abbreviated as brandy as early as 1657, but the fuller form was retained in official use down to the end of the seventeenth century. This brande-

wine is the *eau de vie de vin* of the French, the liquid which was the subject of Brande's papers (1811 to 1813) in the *Philosophical Transactions*, and the name brandy is properly restricted to the liquid distilled from the fermented juice of the grape. The well-known smell and flavor of brandy are due to the presence of ethers and aldehydes developed during the process of the maturing of the spirit; of these the most important is enanthic ether, which was discovered by Liebig and Pelvuze in 1836. They found that the body in question can be obtained in wine lees, and they showed that it is the ethyl ether of enanthic acid. Unfortunately this ether can be obtained from castor oil and other substances, so that its presence in no way proves that the liquid containing it is brandy. When the phylloxera oidium, and mildew, whose ravages in 1875 reduced the area under vineyards from six millions and a half of acres to less than three millions, the supply of grapes in the country round Cognac, in Charente, in the west of France, became insufficient to meet the demand for brandy; even the Armagnac district failed to meet the demand, and potato spirit, beetroot spirit, and grain spirit flavored with emanthic ether, colored with ergot and generally sophisticated, came to replace the true brandy in the British market. This substitute possessing none of the medicinal properties of cognac brandy, is capable of doing serious injury to any patient to whom it may unwittingly be given. We see no reason why the imports of brandy should not be submitted to examination from time to time, and the so-called 'trade' brandy destroyed at the port of entry. Until this is done the physician can protect his patient in no other way than by prescribing the liquor bottled by houses of repute in the trade, and, happily, there are several firms whose brands are trustworthy, and whose brandies can be prescribed with the confidence begotten of years that the patient will get true brande-wine — the liquor distilled from the fermented juice of the grape."

MEDICAL GENERALS.

Apropos the nomination of General Wood to be a brigadier general in the regular army, it is an interesting fact that he is not the first surgeon who has made a high military reputation on being transferred from the staff to the line. General Samuel W. Crawford at the outbreak of the Civil War was a captain and assistant surgeon stationed at Fort Sumter. As one of Major Anderson's officers he took more than a surgeon's share in the defence of the fort, actually commanding one of the batteries that responded to the Confederate fire.

Transferred to the line of the regular army, he accepted a brigadier's commission in the volunteers and subsequently rose to the command of a division, serving with distinguished credit at Gettysburg and in Grant's Virginia campaign. After the war, in which he won brevet-general rank in the regular army, he long commanded a regiment stationed in the South, actively engaged in the enforcement of the reconstruction laws. General Crawford was generally esteemed a most capable officer, though he did not escape the prejudice line officers have against officers who came into the line from a staff corps, as the Medical Department is. Sheridan at one time protested against Crawford's selection for a high command on the ground that he had been a "pill-roller," but had to admit that Crawford was at least an exception.

At no time was General Crawford likely to succeed to the command of the army, and therefore he did not challenge line sentiment to the extent General Wood challenges it. In the natural order of promotions and retirements, Brigadier-General Wood, if confirmed as such, will become Lieutenant-General Wood in 1909, and will not attain retiring age until 1924. It is the prospect of the army being commanded for fifteen years by a lieutenant general who began his military career as a surgeon that ruffles every feather in every chapeau of the army. — *Boston Transcript.*

Obituary.

ARCHIBALD HAMILTON JACOB, M.D.

In the death on January 9th in Dublin, Ireland, of Archibald Hamilton Jacob, B.A., M.D., T.C.D., F.R.C.S.I., medical journalism loses a man of conspicious prominence. He had for many years been connected, as editor, with the *Medical Press and Circular*, a periodical which has taken rank with the best of the English medical journals. He received his degree in medicine in 1862, and was at the time of his death sixty-three years old. His main professional interest apart from journalism was ophthalmology; he had for many years occupied the chair of ophthalmology in the Royal College of Surgeons, Ireland, and also held various hospital positions. The work for which he will be best known, however, was his able and dignified editorship of the *Medical Press*. To this he devoted much of his time. As a conversationalist he was brilliant, and as a man, both in his professional and private life, he filled a large place in the regard of his professional brethren.

Correspondence.

X-LIGHT KILLS.

Mr. Editor: — In the *Electrical Review* for January 5, 1898, I stated that the so-called x-ray burn could be produced by electricity when no x-light was present. Here I show that when electricity is excluded, death can be produced by x-light without burning. A strong male guinea pig was placed in a grounded Faraday chamber and exposed to x-light for two hours a day, the source of light being outside. He died on the eleventh day. The experiment was repeated, with death on the eighth day. No burns in either case. There were many details connected with these experiments which are not given, for I remember how many hours of sunlight I have lost through being obliged to read long papers. I try to get this note printed in a medical instead of a physical journal, where the others of the series have appeared, for several reasons: (1) Because the experiments separated the effects of electricity from those of x-light and showed clearly what a powerful agent x-light was. (2) To call attention to need of using this power in new growths in the interior of the body. (3) To give an opportunity to repeat three precautions I have advised: (*a*) the physician in using the fluoroscope should wear glasses of the most non-radiable material that is transparent; (*b*) the x-light tube should be in a non-radiable box from which no x-light can escape except the smallest cone of rays which will cover the area to be examined, treated or photographed; (*c*) the patient should be covered with a non-radiable material, exposing only the necessary area.

Very truly yours,
William Rollins.

METEOROLOGICAL RECORD

For the week ending February 2d, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Newburyport	14,478	7	1	28.58	—	—	—	—
Melrose	12,962	7	—	—	28.58	—	—	—

Deaths reported 3,032; under five years of age 765; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 765, consumption 387, acute lung diseases 331, diphtheria and croup 91, diarrheal diseases 69, influenza 56, typhoid fever 45, scarlet fever 33, whooping cough 19, cerebrospinal meningitis 9, measles 4.

From whooping cough New York 8, Pittsburg 3, Philadelphia and Somerville 2 each, Baltimore, Worcester, Lowell, and Cambridge 1 each. From cerebrospinal meningitis Worcester 4, Gloucester 2, Boston, Lynn and Everett 1 each. From scarlet fever New York 14, Boston 9, Philadelphia 6, Lynn, Somerville, Salem and Holyoke 1 each. From measles New York 2, Philadelphia and Boston 1 each. From typhoid fever New York 15, Philadelphia 9, Pittsburg and Boston 6 each, Baltimore 5, Lowell, Springfield, Salem and Chelsea 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,789,099, for the week ending January 19th, the death rate was 19.1. Deaths reported 4,320: acute diseases of the respiratory organs (London) 422, whooping cough 99, diphtheria 95, measles 79, fever 38, diarrhea 36, scarlet fever 27.

The death rates ranged from 13.9 in Croydon to 24.8 in Sunderland: Birmingham 21.8, Bradford 15.8, Brighton 19.6, Bristol 19.0, Cardiff 14.1, Derby 16.7, Halifax 15.1, Hull 21.2, Leeds 21.3, Liverpool 23.4, London 18.7, Manchester 20.4, Newcastle-on-Tyne 18.0, Norwich 18.8, Nottingham 18.9, Plymouth 22.1, Portsmouth 16.0, Sheffield 20.3, Swansea 23.3, West Ham 14.9.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING FEBRUARY 9, 1901.

J. A. GUTHRIE, passed assistant surgeon, detached from the "Franklin" and to the "New York," February 18th.

A. M. D. MCCORMICK, surgeon, detached from the Naval Hospital, Norfolk, February 2d, and to the Naval Academy.

R. SPEAR, passed assistant surgeon, detached from the "Buffalo" and to the "Isla de Luzon," on arrival of former at Cavite.

W. B. GROVE, assistant surgeon, detached from the "Vermont" and to the Naval Hospital, New York.

W. H. BUCHER, assistant surgeon, detached from the Naval Hospital, New York, and to duty at the Naval Hospital, Norfolk, Va.

M. V. STONE, assistant surgeon, detached from the "Isla de Luzon" and ordered to the "Buffalo."

E. Z. DERR, medical inspector, ordered to the Naval Academy, February 14th.

W. R. DUBOSE, surgeon, detached from the Naval Academy, February 13th, and ordered to the "Wisconsin."

D. M. BRE[illegible]OLETTE, medical inspector, ordered to the "New York," Feb[illegible]ary 16th.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING FEBRUARY 7, 1901.

BAILHACHE, PRESTON H., surgeon. Relieved from duty as chairman of the board for the physical examination of Second Assistant Engineer R. F. HALPIN, Revenue Cutter Service. February 4, 1901.

VAUGHAN, G. T., surgeon. Detailed as chairman of the board for the physical examination of Second Assistant Engineer R. F. HALPIN, Revenue Cutter Service. February 4, 1901.

CORPUT, G. M., assistant surgeon. Bureau order of January 26th, directing Assistant Surgeon Corput to proceed to Cleveland, O., for temporary duty, revoked. February 2, 1901.

FRANCIS, EDWARD, assistant surgeon. To proceed to Cleveland, O., and assume temporary command of the service during the absence on leave of Surgeon PETTUS. February 2, 1901.

BALLARD, J. C., acting assistant surgeon. Granted leave of absence for five days from February 7th. February 4, 1901.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the society will be held in Sprague Hall, Medical Library Building, 8 The Fenway, on Monday, February 18th, at 8.15 P. M.

Paper: Dr. Abner Post will present the subject of "Accidental Inoculations of Syphilis." The paper will be illustrated by many lantern slides.

ARTHUR K. STONE, M.D., *Secretary*, 657 Boylston Street.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The Section for Clinical Medicine, Pathology and Hygiene will hold a regular meeting Wednesday, February 20, 1901, in Sprague Hall, Boston Medical Library Building, 8 The Fenway, at, 8 P. M.

At 8 o'clock: Dr. C. F. Withington, "Experience with the Widal Reaction in Typhoid."

At 8.15 o'clock: Dr. Charles Harrington: "Dissemination of Typhoid through Oyster Infection."

At 8.30 o'clock: Dr. Calvin Page, "A New Method for the Early Diagnosis of Typhoid." Discussion by Drs. G. B. Shattuck, H. F. Vickery and R. C. Cabot.

HENRY F. HEWES, M.D., *Secretary*.

RECENT DEATH.

HENRY C. HILL, M.D., of Lockport, N. Y., died on February 8th, from Bright's disease, at the age of sixty-nine. He was a native of Vermont and served as assistant surgeon of the 128th Regiment, New York Volunteers, in the Civil War.

Original Articles.

U. S. ARMY PATHOLOGICAL LABORATORIES IN THE PHILIPPINE ISLANDS.[1]

A DESCRIPTION OF THE WORK OF THE ARMY PATHOLOGICAL LABORATORIES AND GENERAL REMARKS ON THE INVESTIGATION OF THE DISEASES OF THE PHILIPPINES.

BY JOSEPH J. CURRY, M.D.,

Acting Assistant Surgeon, U. S. Army; Member of the Board of Army Officers Appointed to Investigate the Diseases of the Philippines.

PATHOLOGICAL LABORATORIES.

THERE were in and near Manila, at the time of my arrival in November, 1899, including the one on the hospital ship *Missouri*, three pathological laboratories. One at the First Reserve Hospital, one on the hospital ship *Relief* and, as mentioned above, one on the hospital ship *Missouri*. The two latter were necessarily small, but were well equipped.

Laboratories on hospital ships. — The laboratory on the hospital ship *Missouri* was located a little forward of midships on the main deck. It was well lighted by four ports, and for night work electric lights on heavy portable stands furnished excellent illumination. The laboratory was furnished with all necessary bacteriological and chemical apparatus, including a thermostat regulated as well as heated by electricity. During the entire voyage from New York to Manila, *via* Suez, the readings of the thermometer in the chamber of the thermostat were noted four times a day. During this voyage we passed from 40° parallel of latitude in the Atlantic to the 2° parallel in the Singapore Straits, and at no time was there a variation of more than $\frac{1}{2}$° C. in the thermostat chamber. The electric heater and regulator was made by the American Electric Heating Company of New York, and was designed by that company. It stood the test of varying temperatures perfectly, and is the ideal method of operating a thermostat on shipboard. In addition to ensuring constant, even temperature it has the advantage of absence of any danger from fire.

As to the advantages of laboratories on hospital ships, in the first place, in smooth water and at anchor, it is possible to do practically the same work as in a laboratory on land. In addition to the value of the laboratory for the purpose of establishing diagnoses in cases on shipboard, the hospital ship, moving as it does to the various ports in the islands, can render the service of a portable laboratory to the cities and the towns the ship reaches. In the case of obscure fevers in other ports than Manila the laboratory of the hospital ship *Relief* has done valuable service. On a trip of the *Relief* to the southern Philippines in March and April, 1900, while Dr. E. R. Hodge, U. S. Army, was in charge of the ship's laboratory, he was enabled by means of it to render valuable service to the medical officers at a number of posts, in performing Widal's test and making examinations of the blood for malaria, etc. In the event of an epidemic in any port distant from Manila the hospital ship laboratory would be invaluable.

In the tropics laboratories are even more of a necessity than in the temperate zones.

[1] Extract from a report to the Surgeon General of the Army on the Diseases of the Philippines.

In a fairly rough sea all examinations, save those with fluid cultures, were made with little trouble. The microscope and electric light stands were kept from slipping about by means of clamps fastened to the working table.

Laboratories in Manila, P. I. — In the earlier days of our occupation of Manila there was little opportunity to establish a laboratory, but at the First Reserve Hospital, soon after its establishment in August, 1898, a small laboratory in charge of Assistant Surgeon McVey, U. S. Army, did valuable work. Unfortunately Assistant Surgeon McVey contracted typhoid fever during his work and died. Assistant Surgeon R. P. Strong continued the work begun by Dr. McVey, and shortly afterwards Professors Flexner and Barker, of Johns Hopkins University, established their headquarters in this laboratory, bringing with them from Hong Kong a full laboratory equipment. The investigations of Professors Flexner and Barker in the laboratory of the First Reserve Hospital stimulated pathological work in Manila.

Additional laboratory apparatus was then obtained from the United States, and when I arrived there December 25, 1899, I found practically all the apparatus necessary for investigation work. At that time there was no other pathological laboratory in the islands. The Manila Board of Health had a building in the walled city which was set apart for a laboratory, but had not yet received a bacteriological equipment. Later, in February, 1900, some bacteriological apparatus was obtained by the Board of Health from the laboratory of the First Reserve Hospital and from the medical purveyor. In May, the Board of Health received from Japan apparatus selected by Assistant Surgeon Calvert during his visit to that country, so that on June 15, 1900, the time of my leaving the Philippines, there were two thoroughly equipped army pathological laboratories in Manila.

The valuable work performed by these laboratories has fully justified the liberality of the surgeon general toward them in the matter of supplies and of equipment. In addition to routine clinical and bacteriological examinations made to establish diagnoses in the cases at the military hospitals, there was conducted, first at the First Reserve Hospital, and later at the Health Board Laboratory, the work on the bubonic plague. At both laboratories investigation work was carried on in other diseases also. Owing to the great amount of routine work there was little time for research work, but still in spite of this, and of a trying climate, considerable was accomplished in this department.

First Reserve Hospital Laboratory. — Here in addition to the routine work of the hospital many blood examinations (including Widal's test for typhoid) were made for other hospitals in Manila. All the dead were brought to the First Reserve Hospital Mortuary, and many autopsies were performed here. There were obtained from these autopsies many specimens of value for the Army Medical Museum. These were turned over to Dr. E. R. Hodge, U. S. Army, who will prepare them and will attend to their shipment to the Army Medical Museum, Washington, D. C.

In the study of the diseases of the islands these laboratory records will be invaluable. It would be of

great advantage if an expert stenographer was attached to the laboratory staff. The climate of the tropics will not permit of the close application to indoor work that is possible in the United States, and the actual time the observer can devote to laboratory work is necessarily shortened. The writing of records takes fully as much time as to do the work and is especially exhausting. The assistance of a stenographer would make it possible for the investigators to devote their entire time to their actual work, and important records now lost would be saved.

For about six weeks from the first of January to the middle of February, 1900, it was necessary to conduct the bacteriological work on bubonic plague at the First Reserve Hospital Laboratory, for the reason that it was the only place at the time equipped for such work. The work on the bubonic plague was abandoned in this laboratory just as soon as the Board of Health established its laboratory.

THE DISEASES OF THE PHILIPPINE ISLANDS.

General remarks. — The Board of Medical Officers to investigate the diseases of the islands followed the recommendations of the surgeon general, and pursued their investigations individually.

Assistant Surgeon Strong had already begun work on dysentery, so this subject was assigned to him. As the work on bubonic plague was under the supervision of the Board of Health, and as Assistant Surgeon W. J. Calvert had performed the greater part of the investigation work, the plague was assigned to him. The study of the fevers of the Philippine Islands was allotted, as special work, to me. Owing to the illness of Assistant Surgeon Strong from December 25, 1899, to February 10, 1900, I was obliged to give nearly all this time to routine laboratory work of the First Reserve Hospital, and had little time to devote to special work. During my service at the First Reserve Hospital, however, I made many visits to the wards, and with the assistance of Dr. E. R. Hodge and Hospital Steward Musgrave, U. S. Army, made many blood examinations. Nearly two months more were taken away from special work by my temporary detail on the Board of Health. Here I unfortunately obtained an infected hand and arm which became troublesome. This was followed later by malarial fever, which finally obliged me to return to the United States. All this interfered with special work, to my great regret.

There were many fevers met with which were not typical in their course. Of these fevers some were of a long duration, but more of from a few days' to a week's duration. These were reported by medical officers under the terms of malarial, dengue, febricula, etc. Many of the short fevers were uninfluenced by quinine administered in large doses. These fevers generally ran their course without regard to treatment, and nothing satisfactory could be learned from the history of their cases. There were a number of long-continued fevers, in which blood examinations were negative. Repeated examinations for the malarial parasites, and Widal's test for typhoid, were negative. Some of these long-continued fevers proved to be Malta fever. It is to be regretted that these obscure fevers could not have been studied more thoroughly. The subject of the fevers of the Philippines is a promising one. The field here is a rich one, and only needs careful, systematic making of blood examinations, combined with clinical observations, to shed more light on many of these now obscure fevers. Further on in this report I will speak more of the atypical fevers.

Bacteriological investigation in the tropics is rendered difficult by the frequency with which cultures become contaminated by air organisms and on account of the rapid putrefactive process in cadavers. Even after the exercise of the greatest care, cultures are frequently contaminated by rapidly growing extraneous organisms. This is especially true of plate cultures. It is a trying condition and adds greatly to the difficulties of the work. It is necessary to make several cultures in the tropics where one usually suffices in the United States.

The bacterial flora of the tropics is apparently as rich and varied as its botanical flora. Many organisms were met with in the course of our work that were unknown to us. Lack of time prevented a careful study of many of these organisms. One fact that struck us forcibly was the frequency of the occurrence of bacilli in the cultures from various local and general infections.

For routine work it was found that agar-agar plate cultures were the most satisfactory. Solidified blood serum slants and agar slants were also used to a limited extent. Gelatine could not be used much on account of the heat.

It was difficult at times, owing to the destruction of so many cattle by rinderpest, which prevailed in the vicinity of Manila, to obtain cow's milk, so that caribou milk had to be used. This was not found to be so satisfactory as cow's milk. Culture media so frequently became contaminated that it was with difficulty that a constant stock of fresh media was kept on hand.

The country is a rich one and not unhealthy for a tropical climate. The diseases of the tropics until very recently have received little scientific study. Heretofore it has been thought generally that the tropics, *per se*, were incompatible with the white man. This is not true. When the same modern sanitary conditions existing in the United States are put in operation in the Philippines, that country will be as habitable as our Southern States.

The records of the First Reserve Hospital from the time of its establishment in August, 1898, to June 1, 1900, show a total of 21,955 admissions from all causes, including wounds and injuries. There were 1,874 admissions on account of wounds and injuries, which leaves 20,081 cases treated in the medical wards of this hospital. The First Reserve Hospital was the first of the army general hospitals established in the Philippines. It was established immediately upon the occupation of Manila and was the main receiving hospital in the islands up to June, 1900. The records of this hospital were remarkably well kept and are very complete. The First Reserve Hospital received most of the sick that came to Manila, not only from stations in Luzon, but also from the southern islands *via* the hospital ship *Relief* and army transports.

The records of this hospital form a fairly accurate medical history of our army in the Philippines. The records of the First Reserve Hospital are especially valuable because of the fact that the diagnoses have been confirmed in so many cases by laboratory examinations. In addition to the numerous examinations of the blood, and of pathological material, there were performed autopsies on most of the cases which died

from March, 1899, to June, 1900. There were 255 post-mortems made during this time, including 98 on dysentery, 40 on typhoid fever, and 9 on the malarial fevers.

DYSENTERIC DISEASES OF THE PHILIPPINE ISLANDS, WITH SPECIAL REFERENCE TO THE AMEBA COLI AS A CAUSATIVE AGENT IN TROPICAL DYSENTERY.[1]

BY JOSEPH J. CURRY, M.D.,

Acting Assistant Surgeon, U. S. Army; Member of the Board of Army Officers Appointed to Investigate the Diseases of the Philippines.

INTESTINAL DISEASES.

Of the 20,081 medical cases treated (August, 1898, to June, 1900) in the First Reserve (Military) Hospital, Manila, P. I., there were 1,999 cases admitted for dysentery, and 2,186 cases for diarrhea, a total of 4,185, or nearly 21% of the total cases. The majority of these cases of diarrhea were probably dysentery. Of the cases which came to the hospital with the diagnosis of diarrhea and died, the post-mortem in most instances showed them to be dysentery. Some of the cases diagnosed as diarrhea proved to be typhoid fever. There were a number of patients who had a moderate diarrhea and who under treatment soon improved and returned to duty. It is safe to say that one-half of these 2,186 cases diagnosed diarrhea were properly dysentery. This would give a total of about 3,000 cases of dysentery, or about 15% of the admissions.

Of other diseases involving the intestinal tract 653 were typhoid fever and 478 may be included under the term "other gastro-intestinal diseases." These latter were for the greater part temporary disturbances of the gastro-intestinal tract, common in the tropics among new arrivals, and mainly the result of injudicious eating and drinking.

Dysentery. — Dysentery is responsible for the highest mortality among our troops on service in the East, but even this statement does not give any adequate idea of the gravity of this disease. In most other diseases there is a limited course, a period of convalescence and the soldier is fit for his usual duty. With dysentery this is not true. For one man who returns to duty and remains well, there are many who return to be sent back to the hospital again and again. Dysentery in the islands is responsible for more *permanent* disabilities than all the rest of the diseases combined. A complete permanent recovery in the islands is the exception to the rule.

It is difficult to say how many of the cases diagnosed diarrhea should be called dysentery, therefore the mortality percentage cannot be given with accuracy. Then, too, many cases of dysentery were transferred to other hospitals and to the hospital ships, and some died on the transport hospitals en route to the United States. There were 132 deaths from dysentery at the First Reserve Hospital up to June 1, 1900. Ninety-eight of these cases of dysentery came to post-mortem. Of these 66 were found to be amebic dysentery, 20 acute dysentery, and 12 subacute dysentery.

Source of infection. — In the great majority of cases among our troops (in practically all the cases I investigated) there was a history of drinking polluted or uncertain water. The almost universal history obtained was that while in the more permanent camps and drinking boiled water the men were free from any serious disturbance of the bowels, but during a march when no boiled water was to be had, the men drank from any stream or pool and diarrhea began.

[1] Extract from a report to the Surgeon General of the Army on the Diseases of the Philippines.

COINCIDENT INFECTIONS.

Malarial fever and dysentery. — The most frequent complication of dysentery in the Philippine Islands is malaria. Malarial attacks are common in the course of chronic dysentery and subacute dysentery. A malarial spleen and active malarial parasites were found in 4 out of 66 cases of chronic amebic dysentery which came to autopsy, and once in 12 cases of subacute (non-amebic) dysentery. In 157 cases of chronic and subacute dysentery among soldiers sick in the First Reserve Hospital, Manila, in which blood examinations were made, the malarial parasites were found in 36, or in nearly 23%. In 1 case of acute dysentery, also, early in the disease, the estivo-autumnal malarial parasites were found.

Typhoid fever and dysentery. — Typhoid fever and amebic dysentery combined occurred twice in the 66 cases. In both cases at autopsy typical lesions of acute typhoid fever were found in the ileum, and there were characteristic ulcers of amebic dysentery in the colon. Microscopic examination of the contents of large intestines in both cases showed the presence of active amebæ, and from the cultures from the spleen and mesenteric glands in both cases the typhoid bacillus was obtained. Widal's test was positive also in each case. One of these cases also had pulmonary tuberculosis. In 1 of these cases perforation of a typhoid ulcer of the ileum was the immediate cause of death. In a third case there were recent healed typhoidal ulcers in the ileum and amebic dysentery.

Pneumonia and dysentery. — Acute lobar pneumonia occurred once in this series of 66 cases of amebic dysentery.

Pulmonary tuberculosis. — There were 2 cases of active and quite extensive pulmonary tuberculosis found in the series of 66 amebic cases. One case was that of a triple infection (amebic dysentery, typhoid fever — acute stage — and pulmonary tuberculosis). In this latter case, which came to autopsy, active amebæ were found in contents of the large intestine and in the scrapings from the typical amebic ulcers of colon. Typhoid bacilli were obtained in cultures from the spleen, and mesenteric glands and cover-slip examinations of caseous contents of lung cavities showed the presence of numerous tubercle bacilli.

Amebic dysentery. — The amebic type occurred in a little over 66% of the cases of dysentery which came to autopsy. Amebic dysentery is the most common type of dysentery found all over the islands. It is responsible for many more deaths than all the other types combined. Its complications and sequelæ are frequent, and it is the most stubborn type in yielding to treatment. It is not my purpose in this report to discuss the etiology of dysenteric diseases of the Philippines. Assistant Surgeon Strong, U. S. Army, will discuss this in his special report, upon which he is now at work. I cannot, however, refrain from expressing my opinion that the ameba coli is a very important etiological factor in the causation of one type of tropical dysentery. In these 66 cases of amebic dysentery there occurred abscess of the liver in 11, or 16⅔%, and in 15, or nearly 25% of these 66 cases, there

was a general peritonitis, due to perforation of ulcer of the colon in 11, and to rupture of liver abscess in 4. In addition to these 15 a general peritonitis occurred once without any perforation of bowel, the infection in this latter case travelling through the thin base of an ulcer in the cecum. (In the 32 cases of non-amebic dysentery there was no case of abscess of the liver, no perforation of the intestine and but 1 of general peritonitis). In all these cases of abscess of the liver active amebæ were demonstrated in both the abscess contents and in the contents of large intestine. Cultures from the liver abscesses were sterile.

The ameba coli: its relation to tropical dysentery.— Whether the ameba coli is primary or secondary, we have the strongest evidence that it *is* certainly a very *important* etiological factor.

There is a disposition recently on the part of many investigators to regard the presence of the ameba coli in the intestine in cases of dysentery as secondary and of itself not an important etiological factor. Several observers have found amebæ, not to be differentiated from the one known as the ameba dysenteriæ, in the stools of those not suffering from dysentery. In other words, they report finding these amebæ in the normal intestines. This is regarded by them as strong evidence against the amebæ as an etiological factor. They believe that the primary trouble in dysentery is started by bacteria and the amebæ then invade the damaged tissue.

It appears that this theory of the secondary and comparatively unimportant part played by the ameba coli in the causation of tropical dysentery rests mainly on the fact that this same organism occurs in the healthy intestine and may exist there some time without causing dysentery. The finding of the ameba in healthy intestines is no more weighty an argument against it as an etiological factor in tropical dysentery than the finding of Klebs-Löffler bacillus in healthy throats is against the Klebs-Löffler bacillus being the causative agent of diphtheria, or the finding of the pneumococcus in the mouths of healthy individuals is against the pneumococcus as the causative agent of acute lobar pneumonia.

It is a well recognized fact that the Klebs-Löffler bacillus often exists in the upper air passages of individuals and they have not diphtheria. It is well known also that the pneumococcus occurs frequently in the mouths of healthy persons. Still the Klebs-Löffler bacillus is accepted by the entire world as the causative agent of diphtheria, and the pneumococcus generally accepted as the causative agent of acute lobar pneumonia.

The fact of the amebæ occurring so frequently in the liver abscesses contents found in the course of tropical dysentery; the absence of bacteria from these abscesses generally; the rarity of abscesses of the liver in the course of dysenteries other than those in which amebæ are present, and the general constant characteristic pathological picture at post-mortem, all weigh strongly in favor of the ameba coli as the principal causative agent in *one type* of tropical dysentery. I speak of *one type* of tropical dysentery because I believe there exist in the tropics, as elsewhere, several varieties of dysentery.

Acute "epidemic" dysentery. — In several of the cases of acute dysentery which came to autopsy during my service at the First Reserve Hospital Laboratory, a bacillus apparently identical with that described by Shiga and by Flexner was found in the cultures. Comparing the cultures obtained from these cases with a culture of Shiga's bacillus dysenteriæ, sent me from Japan by Professor Kitasato, they were apparently identical. I received in March, 1900, from Professor Kitasato, 300 cubic centimetres of anti-dysenteric serum prepared at the Tokio Institute for Infectious Diseases. I am unable to give any opinion as to its efficiency in cases of acute epidemic dysentery, but from Drs. W. J. Calvert and E. R. Hodge, U. S. Army, who have visited the Tokio Institute, I learn that this serum has given remarkably good results. Dr. Hodge, who spent a month October last in Japan, and visited the Tokio Institute for Infectious Diseases, writes me that the results in acute epidemic dysentery with this serum are second only to the results obtained with diphtheritic antitoxin.

We have observed two distinct types of dysentery in the Philippines, one amebic dysentery and the other an acute dysentery, in a number of cases of which the bacillus dysenteriæ of Shiga occurred. In addition to these two types, we have met cases of sub-acute and chronic dysentery in which neither the ameba coli nor the bacillus dysenteriæ were found.

UTERINE FIBROIDS.

BY HOMER GAGE, A.M., M.D., WORCESTER, MASS.,
Surgeon to Worcester City, Memorial and St. Vincent's Hospitals.

THE frequency with which fibromyomata occur in the uterus has always made them a subject of great interest as well as great importance. Fortunately they are often unassociated with any serious discomfort, and remain undetected during the lifetime of their possessor. How often this is true will be appreciated when we consider that from the study of a very large number of autopsies Boyle concludes that they are present in 20% of all women over thirty-five years old, while in women of fifty Kolb estimates their occurrence at 40%. On the other hand, Faultain examined the records of 2,230 gynecological cases at the Edinburgh Royal Infirmary, and found that in only 8% was fibromyoma the assigned cause of their condition. At the Memorial Hospital for women and children in this city, out of 1,724 gynecological cases 131, or 7.6%, were due to the presence of fibroid. A somewhat larger percentage might be found in other localities and in the private records of specialists to whom were referred only the severer cases, but the apparent discrepancy in these figures, it will, I think, be generally admitted, is to be explained by the very large number of cases in which the growths never attain any considerable size or give rise to any special discomfort. The mere presence of such a tumor accidentally discovered need not, therefore, be the occasion of any alarm, nor should it be made the excuse for surgical interference. On the other hand, fibromyomata may undergo degenerative changes that imperil the life of the individual or give rise to symptoms that place her in a condition of chronic invalidism. The discrimination between those cases which can safely be left alone and those which ought to be surgically treated constitutes a problem of the greatest interest and importance, while it is almost equally important and difficult to make a choice among the various measures proposed for their relief.

With regard to those fibroids which give rise to severe and exhausting hemorrhages (and this includes nearly all of the submucous as well as many of the interstitial forms), there is little opportunity for any difference of opinion. Some active interference is almost always necessary — always if it cannot be readily controlled and progressively diminished by the use of ergot, hydrastis, and similar uterine hemostatics. Interference is equally demanded in the rapidly growing forms. Rapidity of growth suggests at once the possibility of cystic or other degeneration, is apt to interfere with the natural duties and activities of the patient, and very likely to cause early impairment of her general health. It is true that this growth may diminish or even stop naturally at any time, but in view of the uncertainty of any such fortunate occurrence and the certainty of being able to deal more easily and more safely with a smaller than with a larger tumor, I think it unwise to postpone operation. Persistent pain, interference by reason of its size with the functions of bladder or rectum, and ureteral obstruction, are less common, but equally positive, indications for surgical intervention. I believe the moral effect of the knowledge of the existence of such a tumor on the part of the patient is oftentimes a very important factor in determining the necessity of operation. Upon some temperaments the knowledge of its existence, provided it were otherwise harmless, would have little influence, but upon others it alone would be sufficient to cause a state of permanent invalidism. I am well aware that this is an indication which may easily be made the excuse for operating in every case, but although liable to abuse, I am convinced that at the hands of a careful, conscientious operator it is a factor always worthy of consideration. Menstrual irregularities and dysmenorrhea, and the multitude of reflex disturbances that are sometimes rightly and perhaps as often wrongly attributed to the presence of fibroids, constitute problems the correct interpretation of which must always be among the most puzzling and most difficult duties of the physician. They are often the principal symptoms for which the patient seeks relief. When they are the only ones, unless their connection with the growth seems very clear, all reasonable means should be exhausted before advising its removal.

It has always been the custom to consider the age of the patient as an important factor in determining the necessity of operation, and it is perhaps as true now as ever that the younger the patient, other things being equal, the stronger the indication for surgical interference. On the theory that the growth of fibroids ceased with the menopause, it has been commonly held that if a patient has approached somewhere near the time when the menopause should be expected, she should be made as comfortable as possible by palliative measures or by simple surgical expedients, and thus tided along until nature shall have effected the cure. Further investigations, however, show that this is by no means always true, that fibroids continue their growth independently of the menopause. Kattmann, in a study of 400 cases, found that in nearly 25% neither climacteric nor menopause had any hindering influence on their growth. This is especially true of those which have undergone cystic degeneration. Another factor of almost equal importance in this connection is the effect of fibroids to delay and prolong the menopause, an effect particularly trying to the patience as well as to the strength of the patient. In view of these possibilities, I have felt that age should be given a place of very minor consideration in determining the question of operation, and have preferred to decide that question upon the evidence derived from its history and symptoms in the way I have already referred to, and without any special reference to the patient's age — the age of the tumor, its activity and its influence seem to me very much more important than the age of its possessor.

In a very hurried and general sort of way, I have rehearsed the chief factors upon which I should decide for or against operation in any given case as it presented itself to me. When surgical interference has been deemed necessary, one is brought face to face with the problem of choosing which of several methods is best adapted to each individual case. It would be difficult here, as in most surgical problems, to lay down hard and fast rules for our guidance. I do not intend to try to do that, but I thought it would be interesting, if not profitable, to take up my own experience with the different methods of operating, their results, and some of the impressions that experience has made upon me. I find that I have dealt with uterine fibroids by dilatation and curettement, by removing submucous forms piecemeal through the dilated cervix by tubo-ovariotomy, by hysteromyomectomy (vaginal and abdominal), and by myomectomy. In all there are 50 cases, with 3 deaths. The ideal operation would be one that was at once safe and free from permanent mutilation. Dilatation and curettement answers both these requirements, and is the simplest of the various surgical procedures which we have to consider. It is undertaken only when hemorrhage becomes a factor so important as to demand relief, and yet not sufficiently severe to require more radical interference. I have resorted to it in 5 cases. In 1, a woman forty-three years old, whose periods of flowing were longer than the intervals, a very small fibroid was found at the fundus and scraped away. There has been a very decided improvement in the matter of hemorrhage, but smaller interstitial nodules have since enlarged so much as to almost fill the pelvis, and give rise to pressure symptoms causing great annoyance. I think it not improbable that further interference will be necessary, unless the menopause, which ought to come soon, shall arrest their growth. In a second case in addition to curetting, I steamed the uterine cavity according to the method of Johnson, of Boston, two periods of forty seconds each, but though there were no subsequent hemorrhages, the brown, watery discharge which had existed for several months continued as before.

Microscopical examination of the scrapings in this case, by Dr. Baker, led to a suspicion of their malignant origin, and the uterus was subsequently removed through the vagina. Its section disclosed a fibroid of the interstitial variety situated in the fundus about as large as a robin's egg. The degenerative changes in the endometrium were of the chronic inflammatory type, not malignant. The patient made a prompt recovery, but remains in a state of extreme mental depression, which has existed ever since the uterine discharge first appeared. In this case all the symptoms, discharge, hemorrhage and mental depression, had come on years subsequent to the menopause. A third case returned to the hospital with request for removal of

the tumor. The symptoms seemed hardly to justify so radical a measure, and her request was denied by my colleague who saw her at that time, and she has since been lost sight of. The other 2 cases were relieved of their symptoms, but their subsequent history after two or three months is unknown.

One of the cases in which I removed a submucous fibroid through the cervix had been previously curetted with little or no benefit. As a means of gaining time — as in waiting for the menopause, or in preparing the patient for a more serious operation — curettement undoubtedly has its advantages, but the results are often unsatisfactory, and are usually followed by a recurrence of the symptoms. It seems to me to be indicated chiefly in young women, when it is our duty to make every effort to preserve the uterus and appendages. The hemorrhage may be due to a small submucous fibroid, which may be removed or its subsequent delivery *per vaginam* favored by the curette. But its field of usefulness is, it seems to me, pretty limited, and likely to grow smaller. Closely allied to this is the operation for the removal of those fibroids which project into the uterus by dragging them down through the dilated cervix and cutting them away piece by piece. I have had 13 of these cases, and while there has been no death, I have had serious septic complications in several of them. Besides general sepsis, I have had in 3 cases a greater or less degree of phlebitis affecting the femoral vein. Some of these cases come to us already septic from the sloughing of the superficial portions of the tumor, others become septic through the sloughing of the shreds of tissue which it is almost impossible to avoid leaving behind in the uterus. Occasionally, as in 2 of my cases, the removal of the submucous tumor is but a partial relief owing to the presence and subsequent growth of other nodules. In spite of its imperfections, however, this will always be the option of election in the great majority of these cases. They are the tumors that give rise to the most severe hemorrhages, and often to the most severe pain. The operation does not mutilate, and in the majority of cases gives permanent relief. Care must be taken to avoid cutting through the uterine wall, and it may be necessary to secure additional room by splitting the cervix on each side; otherwise the technique is simple, though the time necessarily consumed is apt to be very exhausting both to patient and to operator.

To prevent hemorrhage, and produce an atrophy of the fibroids as well as of the uterus, Tait in 1892 proposed to secure an artificial menopause by the removal of the tubes and ovaries. The safety and simplicity of the operation at once made it very attractive, so attractive that it was soon resorted to by all sorts of operators for all sorts of conditions. The reaction caused by its abuse, and the improvement in the technique of the more radical operations, have since pushed this into the background. I have performed it 3 times for the relief of fibromyomata. First in 1892, upon a Swedish woman forty years old, who complained of pain, irregular and profuse menstruation, dyspnea on exertion, nausea and headache. The blood count showed a profound anemia, and there was a systolic murmur at the apex of the heart. Surgically she made an excellent recovery, but ten days after the operation began to show signs of mental derangement, and a month later was committed to the Worcester Lunatic Hospital. Fourteen months later she was sent back to Sweden by the State authorities, and at that time was reported by the hospital physician to be "much improved and in a fair way to recover." Fortunately such an outcome is not common after removal of the uterus or its appendages, perhaps not more common than at the natural menopause, but common enough to be a wholesome check on its too universal adoption.

My second operation was in 1893, upon a nurse thirty-three years old, who, though dependent upon her own work for a livelihood, had been obliged to give up nursing on account of severe pain and hemorrhage at the menstrual periods. Her recovery was in every way satisfactory. She has been well, strong, and abundantly able to practise her profession ever since.

The third case was in 1899. The patient was forty years old, and had had a submucous fibroid removed seven years before at the Memorial Hospital. Since then she had been delivered of a living child, but for two years had been subject to severe and exhausting hemorrhages, until she was unable to leave her house or attend to her household duties, and was much of the time confined to her bed. The tumor seemed to be interstitial, and to occupy the fundus of the uterus. She was so extremely anemic, and so very weak, that I did not dare attempt hysterectomy. I was able to remove the tubes and ovaries easily and rapidly, without any loss of blood and without shock. The result was exceedingly satisfactory. She began to gain at once and gained rapidly in flesh and strength. In a few weeks her health was restored, and she has remained well.

The mortality from this operation in Tait's hands was, for the first 272 cases, 4½%. I think, however, that the mortality today ought not to be more than 1 or 2% at the most. Forty-one out of 50 of his cases that were followed up for six years were in perfect health, and in 14 of them the tumor had entirely disappeared. The occasional persistence of menstruation after the operation, and the knowledge that after all the cause of the trouble has been left behind, with the wonderful improvement in the technique and consequent safety of hysteromyomectomy, have had a tendency to cause tubo-ovariotomy to be wholly overlooked. In just such cases as the last one which I have recited, I believe it possesses very great advantages over the major operation. It can be done more rapidly, with less hemorrhage and less shock. Whenever these factors are of especial importance, and the appendages can be readily isolated, their removal alone is surely worth considering.

I have removed the uterus twice by the vaginal route when it has contained fibromyomata. In 1 case, which has already been mentioned, the operation followed an unsuccessful currettement, and it was undertaken in the expectation of finding adenocarcinoma of the body of the uterus. The fibroid was unexpected. The other case was undertaken for a supposed carcinomatous degeneration of the cervix in September last; three pedunculated, subperitoneal fibroids as large as walnuts were found attached about the fundus. She made a good recovery. Neither of these operations was undertaken primarily for the relief of the fibroids, and as the vaginal route has never been a favorite with me, I should never choose it for that purpose. It is applicable only for the removal of small tumors, and to my mind is not

as exact nor as satisfactory as the operation from above.

I have performed abdominal hysteromyomectomy 25 times, with 3 deaths; 2 of these were the fault of the technique of the operation. The first was that of a woman thirty-five years old, who died of septic peritonitis on the fifth day after the removal for a six-pound tumor. The operation was uncomplicated, and as no autopsy was permitted, I am wholly at loss to account for the fatal result. It could occur, however, only as the result of some error in my aseptic technique. The second occurred in the case of a woman fifty-three years old after the removal of a tumor about as large as a grape fruit; death resulted from general sepsis, which had its origin in an abscess of the abdominal wall. There was no peritoneal or intra-abdominal infection, but the pus burrowed in every direction in a fat abdominal wall, and resisted all the attempts which were made to control it. The occurrence of the abscess was in itself evidence of infection, and whether attributable to unclean suture material or not, was wholly preventable. I have always felt, too, that a better appreciation of the possible dangers would have prompted freer openings at the first discovery of the trouble, and perhaps averted the fatal result. In any event, I think the accident very unlikely to be repeated. The third death followed an operation done a week ago today, in which I removed an ovarian cyst of very large dimensions, completely filling the abdominal cavity, and at the same time a fibromyoma as large as a baseball. The patient was a feeble-minded woman of forty-six years, who was very anemic, but seemed otherwise in very fair condition. She had no vomiting, no pain, no tenderness, and no distention, but failed steadily, both mentally and physically, and died on the fourth day. No autopsy could be obtained. I have since learned that for years she had been unable to pass urine voluntarily, and had been dependent wholly upon a catheter, and that the condition of mind was not natural, but had been gradually coming on for several weeks. The urine was of very low specific gravity, but contained no albumin. I have no doubt that she died from the effect of chronic changes in the kidneys, and that she really was an unsuitable case for operation.

Homans places the mortality after hysteromyomectomy at from 3% to 10%. Doyen collected 147 cases, with a mortality of 4½%. Grieg Smith had 41 consecutively successful cases, and many American operators have reported an equally low percentage of fatal results. These, compared with the mortality of 30% in 539 German cases operated on prior to 1890, show how much has been accomplished by improved technique in depriving the operation of its dangers, and widening the field within which it may be safely advised. From my own experience, I think I approach the operation today with as little fear as five years ago I felt about the simple removal of uterine appendages. It is true that adhesions or other serious complications may be encountered most unexpectedly, but their very presence means a serious condition without operation, and is therefore, relatively considered, no objection. My own method of procedure is to cut the broad ligaments between two clamps down to the attachment of the round ligament, divide the peritoneum over the uterus from side to side at this level and strip it back, keeping close to the uterus until I can feel the uterine arteries between the peritoneal folds, secure these with silk ligatures, and then amputate the cervix. I cauterize the divided uterine canal, secure the ovarian arteries and then the vessels of the round ligament, and finally unite the anterior and posterior layers of the peritoneum by continuous suture from one side of the pelvis to the other. The most important steps are, I think, the absolute control of all hemorrhages about the stump so that there shall be no accumulation of clotted blood in the space between the stump of the cervix and its new peritoneal covering, and the treatment of the uterine canal. During the past year I have tried whenever possible to leave at least one ovary, on the theory that it diminishes the shock of the abruptly induced menopause, but I must confess that I have failed to observe any noticeable difference in the results.

Its progressively diminishing mortality and its completeness make this operation almost ideal in its results when performed for the relief of symptoms definitely due to the presence of a fibroid tumor. It would be ideal if it were not for the fact that it unsexes the patient, and produces a condition which, though compatible with health, is contrary to the provisions of nature. This objection is of especial force in the case of young women under thirty years of age, and has been very strongly set forth in a recent article by Dr. Richardson, of Boston. Fibromyomata are, like lipomata, encapsulated tumors showing no tendency to recur, and the ideal way to deal with them would be by enucleation, just as one deals with the fatty tumors on the surface of the body. In this way their attendant symptoms would be relieved, and at the same time the functions of the uterus and its appendages fully restored. The operation of myomectomy has been generally and successfully employed in pedunculated fibroids, when the pedicle has been small. Should we not extend it still further to those sessile and interstitial tumors which are capable of enucleation? On this subject, in his last edition, Grieg Smith says that "Schroeder identified himself with the practice of enucleation of fibroids, and obtained fair results, but other surgeons have not been prone to follow his example. Theoretically it is admissible, but practically its mortality is high."

The only danger beyond that incurred in any intra-pelvic operations is from hemorrhage, and the supposed difficulty of controlling the bleeding from the torn uterine muscle — simply a matter of technique; and every year is bringing additional testimony to the unsoundness of this objection. Kelly, of Johns Hopkins, has done much to extend the field of this operation, removing successfully in one case nine and in another twelve small uterine fibroids by enucleation. He says that "no more important advances can be made by the gynecologist in the immediate future than by extending the indications for myomectomy and narrowing the field of hysteromyomectomy." It is contraindicated in extreme anemia, when it is desirable to avoid a protracted operation, in the presence of extensive pelvic inflammation, and when the uterus is larger than a six months' pregnancy. Kelly says further that "with these few plain limitations, myomectomy within the proper age limit must always be the operation of election, and if hysteromyomectomy is performed, definite reasons must be given for selecting the radical instead of the conservative plan of treat-

ment." As it is applicable only to the smaller growths, it must be undertaken early, and there should be no delay, especially in the case of young women, after it has been made perfectly clear that the fibroid is steadily increasing in size.

I have performed myomectomy now only 6 times, but with most gratifying results. I have thus far selected only the most favorable cases for its trial, but there has been no difficulty at all in controlling the hemorrhage. This is a pretty small experience, but it has been sufficient to convince me that the method is applicable to many cases in which, a few years ago, I should not have thought it possible, and has given me confidence to believe that a steady improvement in technique will still further widen the field for its practice, and will give us, at least in a very large number of cases, a safe, non-mutilating method of dealing with uterine fibroids.

DYSBASIA INTERMITTENS ANGIOSCLEROTICA (INTERMITTENT LAMENESS OF VASCULAR ORIGIN).

BY JAMES J. PUTNAM, M.D., BOSTON.

AMONG the diseases which count as very rare, and so beyond the need of notice, largely, perhaps, because they are unfamiliar, the one which is indicated by the above title deserves a prominent place, and the careful attention of the general practitioner.

First described by Charcot, in 1854, on the basis of a case seen by him while acting as assistant to Bazan, and again, with greater fulness, in subsequent papers, this affection has been the subject of several clinical investigations in Germany, especially by Goldflam and by Erb,[1] but no case has, to my knowledge, been reported in this country.

The symptom complex is fairly simple and uniform, and the description given by Charcot holds today. In brief, the subjects of this disorder, who are usually persons past middle life, are seized, after walking a short distance, occupying perhaps five to ten minutes of time, with a helpless, cramp-like feeling in the legs, so severe as to render further progress impossible, though after a few moments' rest they can do their short stint again. It is not the severity of the pain so much as an actual incapacity for motion, an inhibition, accompanied sometimes with abnormal sensations in the feet, that hampers them.

So long as the patient is at rest and during the first few moments of exertion, everything seems to be in perfect order, but a careful physical examination almost always reveals, it is said, one or more of several co-ordinated signs, all of which point eventually to the same condition — a limitation of the arterial supply to the muscles. Thus one or more pedal arteries and even the popliteals may be found to be without pulsation, and as a consequence of this the foot may be cool and slightly pale, or red, or blue, according to circumstances. It is usually assumed that an arteriosclerosis, due to age, diabetes, gout or syphilis, or in part to alcohol or tobacco, is the fundamental lesion, but as the symptoms sometimes occur even when the arteries are apparently pervious (Erb) it has seemed necessary to invoke also the concurrence of arterial spasm of vasomotor origin, as an occasional or a partial cause of the ischemia. Prolonged and frequent exposure to wet and cold may tend strongly to induce a reflex habit of this sort.

In Charcot's first case a tumor was found compressing the artery in the popliteal space.

Even the larger arteries of the limb may be involved, and the disease may be identical with one from which horses suffer and which has been traced to changes in the abdominal aorta. The arms are never affected.

The characteristic intermittence during rest and recurrence during exertion is probably due to the fact that when the muscles are in use either an unusual supply of blood is needed or a vascular cramp is induced. Such is the *theory* of the pathology.

The disorder is chronic, and though of varying intensity does not tend spontaneously towards recovery. Occasionally, however, considerable improvement may be induced by measures tending to promote the circulation and to check the formation of a morbid habit. The chief means hitherto used with success are potassium iodide, moderate warmth, prolonged galvanism with the feet resting in tubs of warm water, cardiac tonics, and studious avoidance of exciting causes. Analogous measures which might be found useful are massage under the surface of warm water, as suggested by Jacobi for arteriosclerosis in general; local salt and carbonic acid baths, and Baumann's thyreoiodin, which has recently been found of service in other forms of sclerosis of the arteries and for rheumatic and gouty joints.

The suggestion of this arterial condition as a cause calls to mind other nutritional and painful affections of the feet associated with abnormal conditions of the circulation, such as Mitchell's erythromelalgia and kindred disorders, perforating ulcer and gangrene. In Erb's exhaustive paper these and other points are amply discussed.

Why it is that one person has one of these affections, a second person another, is as obscure as is the nature of the curious predispositions that underlie all the neuroses and yet keep them so distinct and make them run so true.

The case that I have to report bears out, in the main, the accuracy of the classical descriptions.

The patient, whom the courtesy of Dr. C. B. Porter enabled me to examine and to treat, is an active and able business man, a gentleman of seventy, with a remarkably good record for soundness of constitution, temperance of habits, and freedom from disease and exposure. He is without signs of nephritis, or diabetes, or cardiac or arterial disease, unless it be that an attack of sudden giddiness in which he was once precipitated forcibly and suddenly from his chair to the floor was due to a cerebral lesion of arterial origin. This is a possible explanation, especially since no aural disorder could be discovered to account for the seizure and since the acute attack was followed by prolonged dizziness, accentuated by movements of the head.

The symptoms of chief interest in the present connection first showed themselves two months before my examination, in the form of an intense sense of muscular fatigue in the legs, amounting almost to pain, which recurred every time the patient walked more than one-eighth of a mile, but quickly passed away with repose. Since then this condition has remained substantially unchanged. The pain is usually felt first in the calf, generally that of the left leg before that of

[1] Deutsch. Zeitschr. f. Nervenkrankh., vol. xiii.

the right, and then spreads upwards, omitting the knees and centring in the neighborhood of the hips. He then feels, although a man of great resolution, as if he must stop, and that if he went on his joints would grow rigid and he could not move. After a rest, or on waking in the morning, he feels perfectly fresh and "as well as ever in his life." Mental work causes no fatigue and he is singularly free from neurasthenic symptoms of all sorts.

On examination the patient was found in good general nutrition and with an appearance of vigorous health. The heart was normal in size and action and there was no unusual accentuation of the second aortic sound. Nothing abnormal was found in the abdomen by palpation. The calf of the left leg was slightly cooler than the right and perhaps a little less firm. The left knee-jerk was slightly less marked than the right. The toes of the left foot could not be flexed dorsad quite so far as those of the right, though in other respects their movements were perfectly normal. The movements at both ankles and knees were normal and equal. The galvanic irritability of the left peroneal nerve was slightly less than that of the right, but there was no certain difference as regards faradic irritability. An examination of the urine had already been made by Dr. Percy Musgrave at Dr. Porter's request and had shown absolutely normal conditions. Only two of the four pedal arteries could be felt to beat and one of these was scarcely recognizable.

The treatment indicated in the earlier part of the paper was at once instituted, and was carried out with thoroughness for many months. First, galvanism was carried through the length of the limb, with the foot resting in a tub of warm water. Then faradism was used in a similar manner, the indications laid down by Erb being followed so far as possible. Finally, a deep vessel was obtained so that the legs could be immersed up to the knees in water, and this was charged with solutions of artificial Nauheim salts of increasing strengths, the temperature of the water being at the same time lowered, day by day, or week by week. Good cutaneous reactions were secured, but the most that can be said for the success of the treatment is that the patient grew no worse during the time of its use.

Finally, after the bath treatment had been abandoned, the patient undertook to give himself morning and night a kneading of the calves, and, apparently through the influence of this treatment, he began soon to improve. Possibly the influence of the summer weather had also something to do with the favorable change, since it occurred in August, but up to that time warmth had not seemed to have any marked effect. The kneading has been persisted in ever since and the improvement has been progressive, so that at the present time the patient can walk one or even two miles without any considerable difficulty.

With regard to the pathology of the disease, I confess to feeling a little doubt as to whether the generalization of Erb and Charcot is wholly satisfactory. A careful examination of the patient's arterial circulation in the feet made before the treatment was begun showed that one of the posterior tibial arteries could be felt distinctly, the other very faintly, while the dorsal arteries could not be recognized. The same conditions obtain since the improvement, with no recognizable difference.

Erb examined the feet of a large number of patients not subjects of this disease, with reference to the circulation, and gives in his paper a table of the results obtained. Sometimes all four arteries could be felt to beat, sometimes three, two, only one or none, and although the inference which he draws is on the whole favorable to the pathological diagnosis which he is inclined to maintain, still it cannot be said that it is as yet established on a firm footing. The theory is an interesting one, but while the disease is clinically well marked, it must be admitted that our means of recognizing the underlying cause are still insufficient. A vascular spasm is perhaps the best explanation.

Clinical Department.

MASSACHUSETTS GENERAL HOSPITAL. CLINICAL MEETING OF THE MEDICAL BOARD.

REGULAR meeting, December 14, 1900, the president, DR. C. B. PORTER, in the chair.

DR. FREDERICK C. SHATTUCK reported a case of

RUPTURE OF THE RIGHT ILIAC ARTERY.

CASE I. Patient, male, seventy-two years of age, born in Arlington, living in Boston, a druggist by occupation, entered the Massachusetts General Hospital December 10, 1900. His family history and habits are unimportant. His previous history without bearing on his present illness. There is no history of syphilis or of alcoholic excess.

Present illness. — Three weeks ago the patient had an attack of pain which he attributed to indigestion. Three days later he complained of a sharp pain in the abdomen accompanied by a good deal of gas in the intestines. He attributed this discomfort to constipation. Bowels were freely moved by drugs with some relief. The next day the pain was situated in the right iliac region, and he was not relieved by medicines prescribed by his physician. For a few days after this he was fairly comfortable. Eight days ago sudden increase in pain in the right iliac region referred somewhat to the right hip and flank. He had no vomiting; slight nausea, with some distention. No chills, fever or sweating. His bowels moved three days before entrance, with some pain, and this pain has persisted more or less to the present time.

Physical examination. — A well-developed man, of fair nourishment. Thoracic examination practically negative. He had a pulse of high tension, with a tortuous and thickened radial artery. His abdomen distended, symmetrical and tympanitic, the right half more resistant than the left, feeling like a bowel filled with gas. In the right iliac fossa there is an indistinct sausage-like mass where there is moderate tenderness; also slight tenderness between the right crest of the ileum and the costal margin. The rectal examination shows an enlarged prostate. No mass could be felt. Patient had a moderate secondary anemia. His pulse was 96, his temperature 99.4°, his respiration 24 at entrance. His urine was 1.023, with the slightest possible trace of albumin; no sugar. Sediment consisted of an occasional hyaline and fine granular cast. At 8.50 P. M., twenty-four hours after entrance, the patient was reported as pulseless, with marked pallor, restless, and covered with cold sweat. His respira-

tion was labored. He was actively stimulated without any reaction, and died within a half hour.

DR. WRIGHT: At the autopsy on this case a very extensive hemorrhage was found, not only in the retroperitoneal tissues of the right iliac fossa, but extending upward in these tissues as far as the upper pole of the right kidney and downward somewhat below the brim of the pelvis. The extravasated blood was large in amount, and had markedly elevated the peritoneum of the right iliac fossa, and also the cecum and ascending colon. Dissection showed very marked arteriosclerotic changes in the abdominal aorta and in the iliac arteries. In the wall of the right common iliac artery an irregular opening, about 5 or 6 millimetres in diameter, with ragged edges, was found. This opening in the wall of the vessel communicated with an irregular cavity immediately outside of the vessel which was perhaps 3 centimetres in greatest diameter. This cavity was lined with an indefinite layer of grayish to reddish tissue, resembling in appearance the substance of a gray-red thrombus. The surface of the lining of this cavity was irregular and somewhat trabeculated. External to the lining of this cavity the hemorrhagic infiltration of the tissue began. The tissues immediately surrounding the ruptured iliac artery were more resistant to the touch than normal, and there was evidence of an increase in the connective tissue of the region.

DR. PUTNAM: I remember a case which Dr. Fitz will recall, a patient I sent to the hospital many years ago who proved to have a dissecting aneurism — exactly what history I do not remember, but in such position as to press upon the anterior crural nerve roots and give rise to intense pain and hyperesthesia of that region. This pulsating mass was felt, and it was thought to be either aneurism or new growth. It proved to be a dissecting aneurism, as I suppose this substantially is.

DR. SHATTUCK: I wish to emphasize the fact that rupture had evidently taken place some weeks ago here, but the growth had been slight until the last, as it were. No pulsation could be felt over this lump.

DR. VICKERY: I saw the case on the day it entered. I had not followed it at all.

DR. SHATTUCK presented a case of

LEAD ENCEPHALOPATHY.

CASE II. Male, forty-four years of age, married, born in Ireland, living in Cambridge, a painter by occupation. His family history and his habits are unimportant. The important fact in his previous history is that since the age of twelve he has had to do with lead, either as a plumber or a painter. Latterly he has been puttying ships, using two-thirds white lead and one-third putty. At twenty-five he had lead colic in Glasgow, and in the United States in 1886 another attack Off and on during all of these years he has had occasional paroxysmal attacks of pain situated in the epigastrium.

Present illness. — Since June he has not been well. He has had more or less resistant constipation, pain in the abdomen of colicky character, relieved by pressure. He has felt rather weak and sometimes staggers in walking; has fallen. He stopped work five weeks ago, as his employers forbade him going on the painter's stage, because of the danger of falling. Has never fallen from the stage, although he has had frequent fits. These attacks in general started fifteen years ago, had a few fits ten years ago, again nine years and five years ago. For the past three years they have increased in frequency, averaging one per week. For the past five weeks he has had three or four attacks a day. They occur most often while he is in bed. He has never injured himself in one of these attacks. At times they represent petit mal, at others grand mal. In the attack he loses consciousness, froths at the mouth and has involuntary micturition.

Physical examination. — He has a suggestion of a lead line. He has no cardiac hypertrophy, no increased tension of pulse. His aortic second sound is accentuated, his reflexes are present, he has no paralysis of any type, his pain and muscle senses and co-ordination are all right. He has a slight hoarseness, a fine tremor, a moderate secondary anemia. Dr. Cheney reports the fundus normal. Dr. Walton reports all symptoms probably due to lead poisoning. His urine is 1.020, acid, slightest trace of albumin, no sugar, and contains a few hyaline casts. Dr. Wood reports much lead present in 2,000 cubic centimetres of urine.

He has had two kinds of fits — little fits like petit mal. He has had these while on the staging painting. He has also had attacks of grand mal with a cry, with general convulsion followed by unconsciousness. Five weeks ago his employers refused to let him go on the staging any more. I have not observed one of the attacks myself. I saw him once when a little contraction went over the mouth, a sort of flicker, but it did not amount to anything. It seems to be very clear that we have to do here with one of those rather unusual cases of lead encephalopathy, that these convulsive attacks are directly traceable to lead. A rather interesting feature of the case is that he never has had any paralysis. The symptoms have been colic and these convulsive attacks, which, coming on in a man of his age without syphilis, it seems reasonable to attribute to lead. He looks perfectly well. He had an attack of grand mal about an hour ago. The left ventricle is not hypertrophied; there is no arteriosclerosis, and he has not contracted kidney. The fundus of the eye is negative. There is a considerable amount of lead in the urine. He had been taking iodide of potash for some weeks before he came in. We have had two analyses of the urine by Dr. Wood and both showed lead after the administration of the iodide. He has no distinct blue line on the gums.

DR. WALTON: I had the good fortune to see one of these attacks, a typical epileptiform attack, that is, brief duration, a little drooling, unconsciousness, twisting to the left; on coming out he acted rather queerly, as if he did not know where he was or what he was doing. I speak of that because he has some features that resemble hysteria, as cases of lead encephalopathies are apt to do.

DR. F. C. SHATTUCK presented a case of

OSTEO-ARTHRITIS.

CASE III. Patient, age thirty-three, male, single, a roofer, born in Nova Scotia, living in Boston. His family history is unimportant. His habits are good with the exception of a slight tendency to alcoholic excess.

Previous history. — He had the ordinary children's diseases and fifteen years ago had an attack of acute articular rheumatism. Fourteen years ago he had typhoid fever. Ten years ago he had an attack of

gonorrhea, followed in six weeks by rheumatism less severe than his previous attack, lasting longer, but not preventing him from working. Nine years ago a second attack of gonorrhea, followed two months later by return of rheumatic symptoms. From 1890 to 1897 he was able to work, but noticed some stiffness in his back, especially early in the morning. People remarked that he did not bend his back. By November and December of 1897 he could not sneeze or expand his chest without pain; therefore, caught breath and smothered sneeze. In 1899 he was sent to Mexico for lung trouble, where he was said to have muscular rheumatism. Under bath treatment for pains in his chest he gained 8 pounds in three months.

Since November 15th to January 15th he has lost 20 pounds. His physical examination shows a poorly-nourished man, with a paralytic thorax, atrophic pectoralis and shoulder muscles, with complete anchylosis of the spine from the cervical through the lumbar region. Limitation of movement of shoulders from atrophy of muscles rather than from articular change. His chest expansion in the nipple line is 1 inch. He has no anesthesia or paresthesia. He has a moderate secondary anemia and his urine is that of an active hyperemia. No evidence of tuberculosis has ever been obtained. Since his entrance to the hospital he has shown improvement, characterized by greater freedom of movement of his arm and an increase in weight of 10 pounds.

An interesting question is how much his attacks of gonorrhea have to do with the condition. Dr. Goldthwait thinks they play a subordinate part. He has very little power in his deltoids. He cannot put his arms to his head in the manner usual to the normal man. The supraspinatus and intraspinatus are very much atrophied.

DR. JAMES J. PUTNAM demonstrated, from Dr. Shattuck's service, a case of

FRIEDREICH'S ATAXIA.

The patient, a boy of eleven years, had been well up to the age of five, when his present illness first showed itself, except that he had had an attack of scarlet fever. It is also noteworthy, as among possible exciting causes, that he had a severe fall about a month before his ataxia was first noticed, in which he injured the back of his head, at a point still marked by a scar. The case is a highly characteristic one in all respects. The motions of the legs in walking show the curious mixture of choreiform jerkiness, ataxic uncertainty and cerebellar reel, and muscular feebleness, which is so characteristic, and the motions of the hands suggest those of disseminated sclerosis. Nystagmus and tremor of the head are present and the speech shows faint traces of delayed and imperfect enunciation. The knee jerks are absent, while the Babinski reflex is present in a typical form. Sensory disorders are lacking. Even the characteristic extension of the great toe, seen as a part of the deformation of the foot which ends as talipes equinovarus, is present in so far as that when an attempt is made to extend all the toes it is the great toe alone that responds. Scoliosis is not present. No other cases have been noted in the family, but there are only two other children, still young.

Dr. Putnam demonstrated also some sections from a case of this disease of which the record was published by Dr. Everett Smith in 1885, and which he had studied and described for Dr. Smith's paper. They are of some interest as representing the first pathological study of this disease made in this country.

It is truly extraordinary to consider how many forms of ataxia, clinically so distinct, are due to lesions so like in position, and on the whole, in character, within the central nervous system, at least so far as the spinal cord is concerned, and the truth is that what we see is only a gross representation of the changes which actually occur. The essential tendency of the disease is not represented at all by the anatomical conditions and it may be that the subtle disorders of function which are really characteristic are still beyond our ken. Yet the symptom complex of the disease must have its physiological correlate.

I would like to call your attention to the way in which this boy walks with the legs wide apart and yet with a reel. Also, his legs twitch and his hands twitch almost in a way to suggest chorea or, again, so as to suggest disseminated sclerosis, and yet he does not have either one. His gait is wholly different from that of a locomotor ataxic patient, and his nystagmus does not belong to the symptomatology of tabes; yet in some respects the lesions recall those of that disease and some of the signs are similar. The only indication of any nutritional trouble with the foot, such as is common in Friedreich's disease, is this: When he tries to extend the toes he is able to extend the great toe and not the others. It is said that in the families in which this trouble has been prevalent the first sign sometimes noticed is that the great toe is kept extended. He has slight indication of equinus, also, in that the dorsal flexion of the foot is poor; otherwise the feet seem to be in good condition. Mentally he is in perfectly normal condition, intelligent and keen, and would be filling a first-rate place in the world if he could get about a little better. He is eleven years old and has had this trouble six years, the only obvious exciting causes being a fall and the scarlet fever. The knee jerks are absent on both sides. He has a slight Babinski reflex tendency of the toes, which goes with this affection of the lateral tracts.

DR. J. C. WARREN reported a case of

SPLENECTOMY.

CASE I. The case I have to report upon this evening is that of a patient, whom I saw with Dr. Torrey, of Beverly, a year ago, with an enlarged spleen. I shall not go into the details of his case, as I expect to report it later in full. His illness has existed for the last two years, the symptoms being attacks of vomiting, profuse diarrhea and occasional chills. During the past year the tumor has increased considerably in size, and he has lost weight and his condition is not so good. He is incapacitated from doing his work. The blood examination showed white corpuscles, 2,200; red corpuscles, 5,200,000; hemoglobin, 65%. The diagnosis was a slight degree of splenic anemia. The spleen was removed through a long incision along the outer border of the left rectus muscle, the opening being further enlarged by a shorter incision at right angles to it. After dividing the adhesions to the omentum, the tumor was seized by the right hand introduced between it and the diaphragm and turned over, thus exposing the vessels at the hilus. These being clamped, the tumor was removed. The patient made a slow recovery and later developed a pyrexia of several weeks' standing, which is now disappearing.

Dr. Torrey reports that he is doing well. An examination of the blood recently made by Dr. Lord shows a gradual return towards the normal. (Specimen and photograph of abdominal incision shown.)

DR. W. F. WHITNEY'S REPORT.

The spleen was in general of normal shape, but was deeply lobulated along the anterior surface, the lobules measuring 2 or 3 centimetres in depth. It was greatly enlarged, measuring, after removal, 21 centimetres in length by 16 in breadth, and 8 centimetres in thickness. The blood vessels at the hilus were increased in size. The consistency was moderately firm, the color, on section, of a uniform dark red. The trabeculæ were easily recognized and follicles occasionally to be distinguished.

Microscopic examination with low power showed that the trabeculæ were thickened, and the follicles were present, but were small and irregular in shape and diminished in number. The spleen pulp was striking on account of the small number of nuclei which were stained. On examination with a high power, it was found that the reticulum was very much thickened, leaving very small spaces between, in which was only an occasional spleen cell, leucocyte and a few blood corpuscles. The greater number of the nuclei seemed to belong to the reticulum and its lining. The blood vessels showed but little change.

The essential pathological feature lies in the thickening of the reticulum, decrease of the pulp cells, and small size and irregularity of the follicle.

DR. RICHARD CABOT: I should like to ask Dr. Warren what the diagnosis is.

DR. WARREN: Splenic anemia. I presume the etiology of these different forms of enlarged spleen is imperfectly understood. I have not gone into the subject sufficiently yet, and I look to the medical men for a diagnosis rather than to put one forward myself, but that was the diagnosis that was proposed at the time, and it seemed as fairly to meet this case as any other.

DR. RICHARD CABOT: I think the description of the spleen corresponds very closely with what Dr. Osler has described in connection with what he calls splenic anemia. Symptoms of enlarged spleen plus anemia without known cause seem to make up that disease. So far as I know, no good work has yet been done toward putting this disease on a substantial pathological basis.

DR. WARREN, in reply to a question, said that the patient lived in Beverly, was born in Scotland, and that there was nothing to show malarial taint in the case.

Dr. Warren presented 2 cases of operation for

LOOSE SEMILUNAR CARTILAGES.

CASE II. This patient was operated upon about two months ago for attacks of synovitis. The patient had been operated upon by Dr. Harrington in 1896, for a loose piece of cartilage which was removed at that time with great relief. On opening the joint by a vertical incision outside the patella no abnormality was observed in the outer semilunar cartilage, but as it appeared to be more movable than normal and it was in this region that the patient had complained of pain, the cartilage was excised. He now shows you a somewhat unduly movable joint, but he is much relieved by the operation.

CASE III. In this case, operated upon two weeks ago, the patient complained of pain at the back of the joint on the inside, with swelling of joint and frequent disability. A vertical incision exposed the inner cartilage, which was removed entire, showing at its posterior horn a movable flap of cartilage about the size of the little finger nail. The patient has made a rapid recovery, although the knee is still somewhat stiff. The deeper portions of the wound were united by a mattress wire suture, the skin by a buried wire suture and the wound was dressed with silver foil.

PLASTIC OPERATION FOR RODENT ULCER.

CASE IV. Dr. Warren showed a patient, sixty-eight years of age, who had suffered from rodent ulcer for eighteen years. The right side of his face was replaced by cicatricial and epithelial tissue so blended as to make any palliative operation out of the question. The right orbit was invaded by the malignant growth. The operation consisted in an excision of the right half of the face, including the contents of the orbit. The eyebrow and a portion of the upper lip were allowed to remain. The space thus denuded was covered by a flap taken from the bald space on his head. This flap reached to the median line of his nose. During convalescence the patient had an attack of erysipelas. He has now been well a year and has no recurrence.

Dr. Warren showed the case to illustrate how this form of cancer remained localized for great lengths of time, and he also called attention to the necessity of performing a major operation in many of these cases and the hope that it held out for a permanent cure, even in cases which physicians were inclined to regard as too far advanced for further treatment.

Medical Progress.

REPORT ON DERMATOLOGY.

BY JOHN T. BOWEN, M.D., BOSTON.

IMPETIGO, CLINICALLY AND BACTERIOLOGICALLY.

SABOURAUD'S[1] studies are comprised in several papers or divisions. In the first paper he discusses the clinical aspect of the question, pointing out that the clinical varieties of impetigo have not been kept apart by those who have studied the bacteriology. He divides the subject into the impetigo contagiosa of Tilbury Fox, and the follicular impetigo of Bockhart. The impetigo contagiosa of Tilbury Fox begins as an erythematous patch which rapidly becomes a vesicle containing clear fluid. The fluid may or may not become purulent, and a crust is formed quickly, which may increase by the formation of new vesicles about the periphery. The impetigo of Bockhart, on the other hand, is characterized by rounded pustules filled with yellow pus with a hair in the centre. The affection is apt to appear very suddenly and to recur, and to leave behind it furuncles and follicular lesions. Bockhart's impetigo may be and frequently is added to the impetigo contagiosa of Tilbury Fox as a complication. The circular and gyrate impetigos of the face are allied to the impetigo contagiosa of Tilbury Fox,

[1] Ann. de derm. et de syph., January, March, April, 1900.

as is ecthyma also. The question is raised whether a variety of lesions of follicular position, pustular, traumatic and so-called professional forms of dermatitis of the extremities, as well as forms of eczema and lichenification that follow or complicate Bockhart's impetigo, are not due to the same cause.

In his second paper Sabouraud discusses the bacteriology of these forms. He thinks that the chief fault of investigators has been to study the lesions at too late a stage, when there has been a secondary infection, and the second fault that of using solid culture media for the impetigo contagiosa of Tilbury Fox. Liquid media should be used, as the streptococcus is very hard to recognize when associated with other microbes in solid media. His method is to take a drop of serum from beneath the crust by means of a pipette, and to add to this a liquid medium, ascitic serum and bouillon. By this means he has cultivated the streptococcus, and maintains that this organism is present alone in the early stages of the affection, and that the staphylococci do not make their appearance until the purulent stage is reached. As long as the culture of the streptococcus remains pure, the vesicle of impetigo contagiosa is transparent. In the case of ecthyma, there is the same streptococcus and this term designates the same affection as impetigo contagiosa of Tilbury Fox, when seated upon the surface of the body and taking on an ulcerated form. Impetigo contagiosa of Tilbury Fox is readily invaded by staphylococci and then passes into the stage of suppuration.

Sabouraud declares further that whenever an active effusion of serum quickly solidifying into bright yellow crusts appears in any cutaneous affection whatsoever. there is an infection with the streptococcus, — an impetigo contagiosa complicating a seborrheic eczema, a dyshidrosis, a prurigo of Hebra, — in short, any skin affection.

Sabouraud then takes up the second form of impetigo, the follicular impetigo of Bockhart. This is seen in either a discrete or confluent form, chiefly in the regions where hairs are present, as on the scalp of the infant or the moustache and beard of man. The lesions may be large and small on the same subject. They may appear without known exciting cause, or secondarily to a traumatism or a pre-existent microbic infection. Often they are due to a chemical agent, such as turpentine; and the pustular eruptions from medicaments, such as mercurial ointment and croton oil, oil of cade, etc., are included by Sabouraud in this class. All of these impetiginous eruptions he regards as caused by the staphylococcus aureus, the creator of this whole group of affections, of which the type is the impetigo of Bockhart. He goes even further and declares that the acne pilaris of the adult and acne necrotica are impetigos of Bockhart added to a seborrheic infection, as well as the septic inflammatory affections about the nails. When the two forms of impetigo are allied and become chronic they give rise to the appearances usually designated as chronic eczema.

PROTOZOIC DERMATITIS.

Montgomery,[2] of San Francisco, contributes a new case of this interesting affection. The patient, a man of twenty-one, entered the hospital in San Francisco suffering apparently from pulmonary consumption.

[2] British Journal of Dermatology, October, 1900.

He was born in Germany of German parents and came to San Francisco when three years of age, and had remained in this country ever since. For the past two years he had been a telegraph operator and in this capacity had worked in various places along the railway in California. About seven or eight months previous to entering the hospital he had developed a cough. The skin lesions were just beginning to develop when he entered the hospital, the first one to show itself being over the right eye. The cough was growing steadily worse, he had night sweats, and had lost considerable weight. He presented the general aspect of a consumptive. Examination of the chest showed sharp vesicular breathing at the left apex, and bronchial breathing and crepitant râles at right apex, but no tubercle bacilli could be found in the sputum, which was considerable in amount. A month after entering the hospital, the signs in the lungs had increased, the spleen was enlarged, and one of the cervical lymphatic glands was enlarged. The skin lesions, which were situated on the head and extremities, began as dark rounded nodules, with suppuration at their summits, which soon became ulcerated. Some of these nodules were quite large, projecting well out from the skin, and were constricted at their base, resembling somewhat the fungous tumors of mycosis fungoides and iodide and bromide poisoning.

One of the nodules was cut out and showed a granulation tissue with giant cells, and numerous small abscesses scattered through it. A micro-organism similar to that found by Rixford and Gilchrist was found in the granulation tissue and in the giant cells, but was very rarely present in the abscesses. It commonly possessed a clear double-contoured capsule, which enclosed a sphere of protoplasm having a dark periphery and a lighter centre. In another form the capsule enclosed large numbers of spherules due undoubtedly to spore formation. In some cases the capsule was broken and the spores could be seen escaping from it. Inoculation of a rabbit proved negative. A mould was cultivated on glycerin agar, but was not further studied.

The patient died two months after his admission to the hospital, and at the autopsy several large abscesses were found, over the frontal bone and above the clavicle. The latter was found to communicate with the right pleural cavity and with a large abscess occupying the upper part of the right lung. There were several other abscesses in the lung, and an immense abscess of the liver. In all of these abscesses the protozoic organisms found in the skin were present.

Wernicke, of Buenos Ayres, reported the first case of this disease in 1890, and was followed by Rixford with 2 cases, with pathological examination by Gilchrist, in 1895. In all these cases fungoid lesions were present on the skin, which contained these protozoic bodies. The next case was in 1897 by Posadas, of Buenos Ayres. In 1900 Ophüls and Moffitt published a case where the fungous tumors of the skin were not present, but the abscess formation was the same, and from this they cultivated a fungus which caused the disease when inoculated into guinea pigs.

Five of the reported cases have been in men. Three of the cases were Portuguese from the Azores, and four of them had lived in California for a longer or shorter time, so that Montgomery regards California as the habitat of the parasite. Montgomery's case

had lived for a long time in the San Joaquin Valley in California, where Rixford's cases had also lived, while Ophüls and Moffitt's case had lived in a valley running parallel. A fact of possible importance in Montgomery's case was that the patient had frequently used, while on the railroad, "car waste" as a bedding, and when he first began to cough was living in Los Baños, near which there is a spring feared by sheep-herders, on account of its alleged property of causing the ewes to drop their lambs. All of the reported cases of this affection have steadily progressed to a fatal termination.

(To be continued.)

Reports of Societies.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

NINETY-FIFTH ANNUAL MEETING, HELD IN ALBANY, JANUARY 29, 30 AND 31, 1901.

(Concluded from No. 7, p. 166.)

THE TONOMETER AND ITS VALUE IN DETERMINING ARTERIAL TENSION.

DR. HENRY L. K. SHAW, of Albany, exhibited and described this instrument.

PLEUROPERICARDIAL AND DIAPHRAGMATIC ADHESIONS.

DR. D. H. GOODWILLIE, of New York, called attention in this paper to the important part played by interpleural pathological conditions. If they were not recognized early and appropriate treatment instituted, the pleuræ would become thickened, and permanent adhesions would form between the pericardium, diaphragm and pleura. The latter were difficult of recognition and serious in their results. The author entered a strong plea for more scientific and systematic training of physicians in auscultation, particularly in the matter of a good working knowledge of the laws of acoustics as applied to the human chest. The position that he took concerning pleuropericardial adhesions had been sustained both by clinical and post-mortem experience, and the same conditions had been found by him in cattle while engaged with a committee of the United States Government in investigating bovine pleuropneumonia. The speaker exhibited beautifully made wax models illustrative of these lesions.

DIFFERENTIAL DIAGNOSIS IN DISEASES OF THE SPINAL CORD.

DR. EDWARD D. FISHER, of New York, discussed this subject. He said that the anterior horns control the nutrition and action of the muscular system, and that any destruction of this region must lead to paralysis and wasting of the muscles affected. As the lateral tracts were essentially motor, disease of those tracts causes only paralysis without wasting. He proposed to classify the diseases under discussion as follows: (1) Diseases of the anterior horns, as poliomyelitis, acute and chronic, progressive muscular atrophy, and hemorrhages into the cord substance, all of which were specially characterized by paralysis with muscular atrophy; (2) diseases of the lateral or crossed pyramidal tracts, as seen in lateral sclerosis following myelitis, injuries, etc., in which there is paralysis without atrophy; (3) diseases of the posterior columns or tracts which, being only sensory in function, give sensory disturbance without paralysis or atrophy, as in tabes.

PUS IN THE PERITONEAL CAVITY.

DR. ROBERT T. MORRIS, of New York, the author of this paper, endeavored to show how much power the peritoneal cavity has in dealing with pus by a process of leucocytosis.

THE INDICATIONS FOR AND LIMITATIONS OF SPINAL COCAINIZATION IN SURGERY.

DR. GEORGE R. FOWLER, of Brooklyn, had prepared a paper on this subject, but, owing to the lateness of the hour, contented himself with presenting a few of the main points.

MASTURBATIONAL NEUROSES.

DR. WILLIAM C. KRAUSS, of Buffalo, gave very briefly his experience with this class of cases.

SECOND DAY.

DR. JOHN H. DOUGHTY, of Matteawan, presented a paper on

APPENDICITIS,

but for lack of time was prevented from reaching the main conclusions.

TENDINITIS AND TENOSYNOVITIS PROLIFERA CALCAREA.

DR. CARL BECK, of New York, reported this case, and presented skiagraphs.

THE TREATMENT OF PUERPERAL FEVER.

DR. HERMAN J. BOLDT, of New York, read this paper. Under the term "puerperal fever" he included acute bacteriemia, chronic bacteriemia, sapremia and local septic infection. Acute bacteriemia he defined to be a blood disease caused by parasitic micro-organisms invading the circulatory system from some primary seat of infection. Chronic bacteriemia was likewise an invasion of the streptococcus pyogenes, but disseminated from an infected thrombus. Sapremia was the result of the absorption of decomposition products in the genital tract — toxins and saprophytes. Acute bacteriemia, he said, was the most serious, causing a mortality of nearly 98%. The prognosis depended upon our ability to remove the putrefactive factors soon after the onset of fever, and before other infection had taken place. In the treatment of puerperal fever one must first enjoin perfect rest, and search for the seat of infection. If the latter were then found to be located about the vagina or vulva, the part should be wiped with absorbent cotton moistened with some antiseptic solution that is not caustic, and then dusted with aristol or some similar antiseptic powder. Where the seat of infection was covered with a grayish-white membrane the case was more serious than where there was simply a free pus formation. If no infection could be found about the entrance to the genital tract, the vaginal mucous membrane and the vaginal portion of the cervix should be minutely inspected, care being taken not to reopen small wounds. If the examination were still negative, and the patient's condition were good, the phy-

sician should wait and watch, remembering that the retained placental tissue was often soon expelled spontaneously. If, however, her condition were not good, the interior of the uterus should be examined under strict antiseptic precautions. He was strongly opposed to the use of the curette in cases of septic endometritis. An intra-uterine douche should be given both before and after the intra-uterine manipulation, and ordinarily it was better not to repeat this douche. The exception to this rule was found in those cases in which the temperature remained high and there was a free purulent discharge from the uterus. He had seen no benefit from the insertion of gauze in the uterus for the sole purpose of securing drainage. If the infection were localized in the pelvic cellular tissue or the pelvic peritoneum, the ice-coil and inunctions of Credé's ointment of metallic silver would be found beneficial. He had not found treatment with antistreptococcus serum of any value.

THE EARLY DIAGNOSIS OF INSANITY.

DR. CARLOS F. MACDONALD read this paper, pointing out the special importance of this subject to the family physician. He said there was no disease which was so likely to be mismanaged in its initial stage as insanity. The symptoms might be summarized as a prolonged departure from the methods of thinking, feeling and acting which were usual to the individual when in mental health. The person must be compared with his own normal mental status. Prominent prodromata of mental disease were morbid emotional manifestations and alterations in the mental characteristics of the individual, and they should always be looked upon as danger signals. Insanity was rarely due to a single predisposing or exciting cause. Many cases of acute insanity could be averted if the prodromata were promptly recognized and treated. Doubtless many minds of the highest order had been irreparably damaged for want of appropriate treatment in the initial stage.

THE RÔLE OF THE INFECTIONS IN WOMEN.

DR. CHARLES A. L. REED, of Cincinnati, O., read a paper with this title, in which he insisted that the essential antecedent condition of an inflammation of any part of the genital tract was an infection. The infection was controlled by the following laws: (1) The epithelial surface of the genital tract when intact is a sufficient barrier to the entrance of micro-organisms; (2) the normal cervix and its secretions are an efficient barrier against the invasion of the uterus by pathogenic bacteria capable of maintaining a habitat in the vagina; (3) the vagina possesses a certain degree of self-disinfection; (4) certain pathogenic bacteria, such as the gonococcus and the Klebs-Löffler bacillus, find here favorable conditions for their growth; (5) pathogenic bacteria, innocuously present in the genital tract, may become virulent when introduced into the underlying structures by an abrasion of the epithelium; (6) pathogenic bacteria when introduced into previously normal tissue immediately set up inflammation; (7) pathogenic bacteria, if not overcome by the leucocytes, may enter the lymphatics, giving rise to metastases and septicemia.

THE PRESIDENT'S ADDRESS. — HERNIA.

DR. A. M. PHELPS, of New York, presented this address, which was a historical sketch of the methods of treating hernia from the Christian era down to the beginning of the twentieth century. His own operation for the radical cure of inguinal hernia had been first published in 1894. The following are claimed to be the points of originality in this operation: (1) The reproduction of large masses of inflammatory material to restore the abdominal parietes, and the introduction of a fine silver-wire filigree throughout the entire inguinal canal, over the transversalis fascia, thus adding to the strength of the weakened abdominal parietes and preventing the new material from stretching; (2) cutting off the hernial sac and, as in any abdominal operation, stitching up the peritoneum and transversalis fascia with a continuous suture of fine silver wire; (3) the use of fine silver wire in a continuous suture.

A HAIR CAST OF THE STOMACH; ITS SUCCESSFUL REMOVAL BY LAPAROTOMY.

DR. NATHAN JACOBSON, of Syracuse, reported this case. The patient was a girl of eleven years, who had presented certain gastric symptoms and finally a nodulated tumor, the lower border of which was on a line with the umbilicus. On abdominal section it had been found that the tumor was within the stomach, and on incising this organ, a kidney-shaped tumor weighing 15 ounces, and presenting a perfect cast of the stomach when in a state of contraction, had been removed. This tumor was found to be composed of hair. The girl admitted after the operation that she had been in the habit for many years of biting off the ends of her hair and swallowing the fragments. All her symptoms had been completely relieved by the operation.

SURGERY OF THE SPLEEN.

DR. J. COLLINS WARREN, of Boston, presented an exhaustive paper on this subject, and reported 4 cases. He gave a long list of diseased conditions for which splenectomy is indicated and stated that with the exception of such grave constitutional disorders as splenic anemia and leukemia and amyloid degeneration the operation of splenectomy could not be said to be contraindicated.

DR. ALEXANDER VAN DER VEER, of Albany, gave some of his experience in the surgery of the spleen, and expressed the wish that it might not be his lot to meet with many cases in this category.

DR. ROBERT T. MORRIS, of New York, called attention to the chief dangers of operations upon the spleen, that is, hemorrhage and shock, and described the best methods of avoiding or minimizing them.

INGUINAL HERNIA.

DR. MELVILLE RICKETTS, of Cincinnati, O., presented in this paper a statistical study of the various methods of so-called radical cure of hernia, and extolled the wire mattress suture used by Phelps.

DR. JOHN A. WYETH, of New York, said that he considered as essential features of a method for the radical cure of inguinal hernia the entire obliteration of the sac and securing the proliferation of newly formed and fibrillated connective tissue. This fibrillation could hardly be secured under six weeks; hence he insisted that the patient should remain quietly on the back for this length of time. The obliteration of the sac he thought was best secured by a modification of Macewen's method.

GASTROJEJUNOSTOMY IN GASTRECTASIS.

DR. A. H. CORDIER, of Kansas City, described this operation, and pointed out its value as a drainage measure.

TOXIN OF THE COLON BACILLUS.

DR. VICTOR C. VAUGHN, of Ann Arbor, Mich., discussed this subject. He said that our present knowledge was lacking in proof that any ptomaine was sufficiently powerful to produce the characteristic symptoms of the disease which had been caused by the germs which produced the ptomaine. Some disease germs, and notably the colon bacillus, had cell walls which were well-nigh impermeable. As a consequence, prolonged exposure to high temperature was not sufficient to set free the toxin contained within the cell wall. By a process of artificial digestion he had finally succeeded in extracting the toxin and exhibited some of it.

THE SO-CALLED TRAUMATIC NEUROSIS.

DR. HAROLD N. MOYER, of Chicago, endeavored in this communication to combat the notion that there is any such thing as a traumatic neurosis, and insisted that such a vague nomenclature was harmful.

THIRD DAY.

The following officers were elected: President, Dr. Henry L. Elsner, Syracuse; Vice President, Dr. Louis N. Lanehart, Hempstead; Secretary, Dr. F. C. Curtis, Albany; Treasurer, Dr. O. D. Ball, Albany.

Recent Literature.

Psychopathia Sexualis, with Especial Reference to Antipathic Sexual Instinct. A Medico-Forensic Study. By R. VON KRAFFT-EBING. The only authorized English translation of the tenth German edition. Pp. xv, 585. Chicago: W. T. Keener & Co. 1900.

If we mistake not, a translation of one of the previous editions of this work was published a few years ago. The present translation is well done and the book itself is extremely well brought out. The original is too well known to require any extended discussion here. It is probably the most complete and scientific study of the aberrations of the sexual instinct that has yet appeared and is based upon the extensive clinical experience of one of the leading alienists of Austria. We miss in this last edition some of the curious letters from patients, giving detailed explanations of their perverse feeling in the true neurasthenic style, flavored with the true German *Schwärmerei* and well stocked with familiar quotations, even though they did detract a little from the scientific value of the work, by causing us to suspect that the explanations were imagined after the fact and were not true depictions of the original state of the patient's mind. Krafft-Ebing's work will doubtless remain the standard authority upon this subject for many years to come, and it merits the careful study of all physicians who have to do with the degenerate, whether these persons be classed as neurotic, insane or criminal. The study of the abnormalities of that mighty instinct which is the basis upon which social advancement is developed, disgusting as those abnormalities sometimes are, is of profound importance in the consideration of many of the problems which physicians who have much to do with the degenerate so often have to meet; and to ignore such study savors more of Pharisaism than of virtue. Nevertheless, the number of cases of sexual perversion actually met with in practice is hardly large enough to create a legitimate demand for ten editions in Germany, or perhaps for a second edition in this country, even though the publishers sanctimoniously announce that it is to be sold only to the medical and legal professions. Valuable as the work is for the true student, we fear that the wide demand for it comes from the sexual neurasthenics and the collectors of pornographic literature. This seems the more probable when we remember how rarely, in the last twenty-five years, any publisher has been willing to take the risk of publishing a translation of any one of the great modern treatises on the whole broad subject of mental disease. If the demand for translations of such works is not great enough in this country to warrant their publication, is it likely that the legitimate demand for a monograph on one limited portion of the subject would be so great as to warrant two editions?

A Manual of Personal Hygiene. Edited by WALTER L. PYLE, A.M., M.D., Assistant Surgeon to Wills Eye Hospital, Philadelphia, etc. Contributors: J. W. COURTNEY, M.D., GEORGE HOWARD FOX, M.D., E. FLETCHER INGALS, M.D., WALTER L. PYLE, M.D., B. ALEXANDER RANDALL, M.D., G. N. STEWART, M.D. (Edin.), CHARLES G. STOCKTON, M.D. Illustrated. Pp. 344. Philadelphia: W. B. Saunders & Co. 1900.

The professed object of this book is to set forth the best means of developing and maintaining physical and mental vigor. To accomplish this end seven men, chosen for their special knowledge, have written on the following topics: Hygiene of the digestive apparatus; of the skin and its appendages; of the vocal and respiratory apparatus; of the ear; of the eye; of the brain and nervous system, and physical exercise. The work has been excellently done; there is no undue repetition and the writers have succeeded unusually well in presenting facts of practical significance based on sound knowledge. The apportionment of space to the various articles is perhaps open to criticism; for example, the eye has 104 pages, the nervous system 39 and physical exercise 22. Important as the eye and its care may be, it is certainly unjust to other subjects to give it nearly a third of the entire book. It should be made more concise in future editions and various tests for defective vision might with much propriety be altogether omitted. One of the best sections of the book is Dr. Courtney's discussion of the hygiene of the nervous system. It is to be regretted that he was not allowed space more in accordance with the importance of his subject. In spite of this limitation he has presented a series of very practical facts in a highly succinct and lucid manner and in so entertaining a form that few will take up his chapter without reading it through to the end. We do not recall a better brief discussion of the vital questions underlying the health and disease of the nervous system. The title of this section is, however, somewhat unfortunate in its wording. Why is not "Hygiene

of the Nervous System" alone sufficient? The addition of the word "brain" appears unnecessary. The book, in general, is undoubtedly a successful venture and should find a wide circle of readers among those for whom it is primarily intended. It is sufficiently well bound and printed and has a considerable number of illustrations which are of value. An excellent table of contents and an index make ready reference possible.

Rudiments of Modern Medical Electricity. Arranged in the Form of Questions and Answers Prepared Especially for Students of Medicine. By S. H. MORRELL, M.D. Pp. 165, with 37 illustrations. New York: Edward R. Pelton. 1900.

The rudiments of modern medical electricity as laid down by the author in this volume do not require the number of pages he employs. They could be summed up in seven words: "Consult my larger work on the subject." The present catechism is made up of questions and answers of a very indefinite sort from which the beginner could learn nothing about the use of electricity. An example may suffice:

"Name an important class of pains that are often best and most curatively treated with selected electric current actions?

"Headaches.

"If the headache is a symptom of any disease that is amenable to treatment by any form of electric current, will the prognosis be a radical cure?

"Yes, if correct methods are employed.

"If the headache is caused by some disease that electricity does not affect, may it abate or remove this symptom without reference to the etiology?

"Yes."

When we add that the writer expresses a firm faith that electricity is a marvellous therapeutic agent in the treatment of bronchitis, Bright's disease, tuberculosis, diabetes and the majority of ills that flesh is heir to, and that he gravely informs us that the Edison street current exceeds the medical unit of the constant galvanic current ten thousand times, we think it needless to waste more time upon a book so wholly worthless.

Introduction to the Study of Medicine. By G. H. ROGER, Professor Extraordinary in the Faculty of Medicine of Paris. Authorized translation by M. S. GABRIEL, M.D., with additions by the author. New York: D. Appleton & Co. 1901.

This book is a reproduction of the course of lectures delivered by the author in 1897–1898 at the University of Paris. The author's object in his teaching and in these pages was to lessen as much as possible the difficulties met with in the study of the medical sciences. This course of lectures was established by the Paris Faculty of Medicine with the view of relieving beginners of much useless embarrassment. The author has had a wide experience both with experimental pathology and with clinical medicine. The translator states that "to read this masterful résumé is to undertake a fascinating journey into those regions of medicine where the most important developments have recently been realized."

The volume, which is an octavo of 545 pages, divided into 24 chapters, with a good general index, will be found a valuable one by the practitioner as well as by the student. The arrangement of the subjects is a judicious one and the author's style is agreeable. The translation seems to be well done. The make-up of the book reflects the usual good work of its publishers.

The Tale of a Field Hospital. By FREDERICK TREVES. With 14 illustrations from original photographs. London, Paris, New York and Melbourne: Cassell and Company, Ltd. 1900.

This small volume of 109 pages is a record of some of the incidents during three months with the Ladysmith Relief Column in South Africa. Mr. Treves was with a field hospital during this time and had ample opportunity for observation, the results of which he has set down in this series of short sketches. The incidents are told in a delightfully entertaining manner and the author has succeeded in presenting to his readers a graphic description of the events behind the fighting line and in the hospital. As might be expected, the pictures are gruesome and often unromantic, savoring little of the glory of war, but as Mr. Treves says: "The account, such as it is, is true." We are duly impressed with the excellent style of the author and the charm of this entire collection of realistic sketches. The book is beautifully bound in flexible covers and equally well printed on exceptionally good paper. The illustrations are reproductions of photographs and add to the general interest of the text.

The Medical Examination for Life Insurance and its Associated Clinical Methods. With chapters on the Insurance of Substandard Lives and Accident Insurance. By CHARLES LYMAN GREENE, M.D., Clinical Professor of Medicine and Physical Diagnosis in the University of Minnesota. With 99 illustrations. Philadelphia: P. Blakiston's Son & Co. 1900.

This book aims (1) to explain the duties of the physician to himself and his insurance company, and (2) to supply necessary information as to how the examination for life insurance should be made from a medical point of view. The numerous minor questions likely to arise, and possibly to prove sources of misunderstanding or friction between the home office and examiner, or disturb his relations with the agent or the applicant, have not been overlooked. Occupation, heredity, conspiracies to defraud have each a separate chapter devoted to them.

An octavo of 426 pages, with index, this book will be found useful by those dealing with or expecting to deal with the medical aspect of life insurance, and some of its chapters will prove interesting to the general medical reader.

Cancer of the Uterus. Its Pathology, Symptomatology, Diagnosis and Treatment; also the Pathology of Diseases of the Endometrium. By THOMAS STEPHEN CULLEN, M.B. (Toronto), Associate Professor of Gynecology in the Johns Hopkins University. With 11 lithographic plates and over 300 colored and black illlustrations in the text. By MAX BRODEL and HERMANN BECKER. New York: D. Appleton & Co. 1900.

This beautifully printed and illustrated monograph forms a volume of nearly 700 large pages. It covers the whole subject of malignant disease of the uterus in the most thorough manner, both from the pathological, diagnostic and operative points of view.

The illustrations are as beautiful and as thoroughly practical as any that we have seen. A work of this class is an addition of real value to medical literature.

THE BOSTON
Medical and Surgical Journal

THURSDAY, FEBRUARY 21, 1901

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

SOME CURIOSITIES OF LEGISLATIVE LITERATURE.

A COLLATION of the bills presented to almost any of our State legislatures for proposed legislation in almost any given field would probably reward the collector in one way or another for his trouble — especially should he possess a humorous sense of the possible tendencies of the human mind in a free, independent and enlightened democratic social organization.

This is perhaps as well illustrated by the suggestions for legislative enactment in regard to matters pertaining directly or indirectly to the public health as by any other. At least this is a favorite field for the well-meaning enthusiast, the chronic agitator, the self seeker under the guise of devotion to the public weal.

It has been our habit to take some note from year to year of bills of this class as presented to the Massachusetts Legislature. The product of this year merits at least passing attention.

We find a bill entitled, "An Act to Establish a Reformatory and Protect the Public Health of the People." It consists of the following sections:

1. A part of the city shall be fenced off for the inmates of houses of prostitution and all other persons of like character for reformation.

2. That a hospital shall be established for their treatment by reputable physicians.

3. That an undenominational church shall be established for their reformation.

4. That they shall wear an insignia, which shall not be concealed, indicating that reformation is not complete until one year has elapsed from the time of the commencing to reform to its completion, when it may be laid aside and the person is permitted to depart.

5. The persons shall pay a suitable sum for rental, clothes, maintenance and the real estate used for this purpose, and these persons shall pay double the assessed value to the State monthly.

An accompanying bill entitled, "An Act to Protect Indigent Women and those Wronged from Great Injury and Suffering," proposes that

1. An undenominational hospital shall be established for treatment.

2. Any person requesting, advertising, aiding or abetting the crime of malpractice or criminal abortion with criminal intent shall be punished as the principal in a fatal case of malpractice or criminal abortion.

5. The poor married woman and the one wronged may be received and allowed to depart with their secrets kept inviolate.

There is a bill designed "to Prevent Premature Encoffinment, Burial or Cremation," which provides as follows:

1. That no person shall place the body of any human being in a coffin, casket, or other receptacle by which air or light is excluded, or by which free movement is prevented, or bury or cremate such body except after certificate of death as hereinafter provided.

2. Whenever any person in any city or town apparently deceases, the board of health of said city or town or the selectmen of such town, if no board of health exists, shall within six hours of such event being known be informed of such apparent death by any person or persons having the body in charge.

3. As soon as is possible after such information the board of health, or said selectmen of such city or town in which such apparent death occurred, shall cause an examination of such body to be made to determine whether death is real or only apparent, and certification of the fact of death shall be not made until the following facts are established by actual tests, wherever possible, namely: (1) Heart signs entirely absent, the test being by the stethoscope; (2) respiratory sounds entirely absent; (3) temperature of the mouth same as that of surrounding air; (4) a bright needle plunged into the body of the biceps muscle, left there, shows no sign of oxidation; (5) intermittent shocks of electricity at different tensions passed by needles into various muscles and groups of muscles give no indication whatever of irritability; (6) fillet test applied to veins of the arm causes no filling of veins on distal side of fillet; (7) opening of vein shows the blood to have undergone coagulation; (8) subcutaneous injection of ammonia causes a dirty brown stain indicative of dissolution; (9) careful movements of the lower jaw and of lower extremities and of occipitofrontalis indicate the presence of rigor mortis; (10) scarlet line (diaphanous test) is absent; (11) decomposition has set in.

And *provided, further*, that, if there is an absence of any of the signs of death except decomposition, all known means of resuscitation shall be tried while such proofs are absent.

4. The test provided for in Section 3 shall be made by not less than two doctors of medicine in person, who shall have lawfully received the degree of M.D., one of whom may be a member of the board of health.

5. No provision of this act shall be construed to prevent any means being used by any person to restore life to the supposed dead body.

6. Every city and town shall provide suitable rooms for the carrying out of the provisions of this act, wherein tests may be made. Said rooms shall contain conveniences for resuscitation of bodies and for funeral services: *provided, however*, that the provisions of this act shall preferably be carried out in the domicile of the supposed deceased, his relatives and friends; but in no case shall any provision of this act be omitted. The expense of said rooms shall be included in the annual expenses of the town and provided

for in the annual appropriation of money for town purposes.

7. The fee for the services provided for in Section 3 shall be fair and reasonable and shall be fixed by the board of health and be at the expense of the town.

9. All laws or parts of laws inconsistent with this act are hereby repealed in so far as they apply to this act, but no farther.

10. Copies of this act shall be conspicuously posted in all cities and towns of this Commonwealth by their respective boards of health.

11. This act shall take effect on its passage.

There is a bill "relative to Compulsory Vaccination" which provides that

Boards of health and other town, city or State officials shall not have the power to compel any man or woman to be vaccinated against his or her consent; neither shall any official have the legal right to order any child to be vaccinated against the will of the child's parent or guardian.

The abuse of the limitations of the existing law in this State already robs the community of some of its good fruits. It is now provided that

No child who has not been duly vaccinated shall be admitted to or connected with a public school, except upon presentation of a certificate signed by a regular practising physician that such child is an unfit subject for vaccination.

It is generally understood that, under this last clause, some individuals licensed to practise do not hesitate to freely furnish such certificates even without seeing the children to whose unfitness they certify, and others regard them as legitimate merchandise to be kept for sale.

A bill "relative to the Vaccination of Children Attending the Public Schools," has been presented to this legislature having for its object the more satisfactory co-operation of school committees and boards of health in this matter.

A bill "to Regulate Vivisection" contains the following sections:

1. It shall be unlawful for any person to perform upon any human patient in a hospital or elsewhere, without the consent of the said patient, a painful or dangerous experiment, except with a view to save the life of the patient, or to inoculate any such patient with disease, for the purpose of experiment, or to administer to such patient a poisonous or dangerous drug for the purpose of experiment.

2. It shall be unlawful for any person not being a doctor of medicine legally qualified to practise as such in this Commonwealth to perform any kind of vivisection or medical or surgical experiment involving pain or discomfort upon any dumb animal.

3. It shall be unlawful to perform upon any dumb animal a painful experiment unless such animal is rendered insensible to pain during the time of the performance of the experiment; but this section shall not be taken to prevent the performance upon a dumb animal of an experiment which produces discomfort as distinguished from actual pain.

4. It shall be unlawful, for the purposes of experiment, to deprive any dumb animal of food for more than twenty-four hours, or of water for more than ten hours.

5. A commissioner of vivisection, nominated by the Massachusetts Society for the Prevention of Cruelty to Animals, and acceptable to the governor, shall annually be appointed by the governor to see that the provisions of this act are enforced. His term of office shall be one year, and he shall serve without compensation.

The said commissioner shall have access at all times to all places where vivisection or animal experimentation is practised or intended to be practised, or where animals are kept which are intended to be used or have been used for vivisection or experimentation; and he shall be permitted freely to inspect such premises and all parts thereof.

7. Whoever violates any provision of this act by performing unlawful vivisection or experimentation, or by preventing or hindering such access and opportunity to inspect as are provided for in Section 6 hereof, shall forfeit a sum not less than $100 nor more than $500 for each offence.

A bill "relative to the State Board of Health" provides that this

board shall have power to make regulations forbidding spitting in public places, including railroad stations and steam and street cars.

There is a somewhat elaborate bill with seven sections designed to provide that

Ice intended for food or drink purposes shall not be composed of water of lower standard of purity than that required for domestic purposes by the State Board of Health.

A bill "for the Establishment of Hospitals for Persons having Smallpox or other Diseases Dangerous to the Public Health in Cities and certain Towns" provides that

1. Cities, and all towns of 5,000 population and over, shall establish within their limits, and be constantly provided with one or more isolation hospitals for the reception of persons having smallpox or other diseases dangerous to the public health. Such hospitals shall be subject to the orders and regulations of the boards of health of such cities and the selectmen of such towns.

2. Whenever the officer of a city or town shall refuse or neglect to carry into effect the provisions of Section 1 of this act, after having requested so to do by the State Board of Health, such city or town shall be liable to forfeit a sum not exceeding $500 for each such refusal or neglect.

Still another bill "relative to the Erection and Maintenance of Pest Houses or Contagious Hospitals by Cities and Towns" makes provision that

No pest house, or contagious hospital, shall be erected or maintained by a city or town within 2,000 feet of the boundary line of any other city or town, without first obtaining the consent of the community affected thereby, and when such permits are granted it shall not exceed a period of five years at any one time, and these permits shall be given only in the following manner, namely, by the consent of the board of health, with the approval of a majority of the members of the board of aldermen of cities, or a majority of the members of the board of selectmen of towns.

An attempt to secure the "Regulation and Control of the Sale and Dispensation of Alcoholic Liquors and certain Poisonous Drugs" sets forth that

1. All alcoholic liquors shall be inspected by skilful persons duly sworn, to their purity, and the poisonous drugs shall be of the "United States Dispensatory" standard.

2. All bottles, glasses and quantities sold or dispensed shall be stamped pure, with the names of the owner and the one who sells alcoholics and poisons, with their sworn affidavit to its standard purity, as described in the "United States Dispensatory."

3. Twice the present price shall be charged for alcoholics, and of the price printed or written on the stamps, two-tenths shall be paid to the United States and three-tenths to the State, five-tenths to the dealer.

4. The right of sale and dispensation of alcoholics shall be obtained by the one who sells, by a petition for and against, signed by a majority of persons residing or doing a legitimate business for three months on the street, within 250 yards of the place of sale and dispensation, and obtained without fraud.

5. Alcoholic liquors shall not be sold within 100 yards of a railroad depot.

7. All may petition against the sale of alcoholic liquors within 250 yards of the place of sale and dispensation, the signers to be eighteen years of age or older, and resident or doing business on said street. The majority of persons shall close or keep open the saloon with sale or dispensation of alcoholic liquors.

A solemn and important looking bill "relative to the Manufacture and Sale of Textile Fabrics and Papers Containing Arsenic," accompanying a petition for an amendment of the existing law, seems to reduce itself to a permit for the manufacture of fly paper.

A bill "to Prevent Substitutions in the Sale of Drugs, Medicines and Articles of Food and Drink," provides that

1. It shall be unlawful for any one, by himself, his agents or servants, in the sale of any article of food or drink, or any drug or medicinal or proprietary preparation, to substitute for or give or deliver for and instead of any such article, drug or preparation bought or called for under any trade or other identifying or distinguishing designation, any article other than the one so bought or called for and designated, without informing the purchaser of such substitution.

The object of this seems to be to control the dispensing by apothecaries or others of "just as good" things.

The bill in support of a petition for authority to grant two degrees — Bachelor of Optics, and Doctor of Physiological Optics — we have already referred to elsewhere.[1]

A few other bills belonging to the class we have selected for notice, especially several relating to the adulteration, substitution or counterfeiting of articles of food or drink, we have passed over. Some of those here cited are grotesque, some are whimsical, some are impractical, some are calculated — perhaps in a modified form — to be of service to our citizens. But the last is not the most numerous division of the four.

A SCHOOL OF TROPICAL MEDICINE IN THE PHILIPPINES.

WHETHER or not the American occupation of the Philippines is to be regarded as a process of beneficent assimilation for the natives at large, it is at least clear that the introduction of modern methods of treating disease is destined to be an unqualified good. Naturally, work in this line has hardly begun, and yet already there is a vigorous demand for more trained men in the medical department of the army of occupation. The usefulness of a physician in this work on tropical disease evidently depends, in great measure, on his preliminary training. Although he may still retain the title of "surgeon," he is very far from that in reality; the demand now is for men whose chief interest lies in that laborious field of study included under the general head of "etiology." Such men must be specially traine in the methods of scientific research, and above all must have a knowledge of bacteriology in the broad sense, or as Dr. Patrick Manson has recently put it, "the student of medicine must be a naturalist before he can hope to become a scientific epidemiologist or pathologist or a capable practitioner. The necessity for this in all departments of medicine is yearly becoming more apparent, but especially so in that section of medicine which relates to tropical disease." How such a consummation is to be attained or approached is the practical question. England and Germany have attempted to solve it by establishing schools, the main function of which shall be the instruction of students and physicians in the subject of tropical disease. These so-called schools of tropical medicine have been carried on with much enthusiasm and with undoubted success, as shown by the increasing number of students, and their eagerness to make practical use of the knowledge they have gained.

The attempt to give such instruction at established medical schools, as a regular part of the curriculum, is not likely to lead to notable results, because the subject has already become too large for cursory treatment, and because the average medical student neither desires nor needs to have knowledge of that character. Special schools are demanded, and, no doubt, will continue to be more and more needed as time goes on. So far as possible it also seems to us desirable that such schools should be established in the habitat of the diseases to be investigated. No doubt a school of tropical medicine in New York or London would attract students and be of value to the cause of progress, but its services would be increased a hundredfold if situated, for example, in India or the Philippines.

As a matter of fact such a suggestion has recently been made for the United States by Dr. J. J. Curry, acting assistant surgeon, U. S. Army. Dr. Curry was one of the army medical officers, appointed some time ago by the Secretary of War, to investigate the diseases of the Philippine Islands; in his report to the surgeon general he makes a strong plea for the establishment of a school for the training of medical men in the diseases of the tropics, at Manila. The school, he says, should be in connection with one of the large military hospitals with a well equipped laboratory attached. "At such a school both clinical

[1] January 24, 1901, p. 98.

and laboratory instruction might be given the new medical officers in the diseases of the tropics, and valuable work on the investigation of tropical diseases might be done. There is great necessity for such instruction, especially as in no medical school in our country are there any courses on tropical medicine." Such a plan would seem on the face of it to be eminently possible, and not by any means an expensive venture. Its usefulness must be unquestioned just at this time of feverish activity in the investigation of epidemic disease. Teachers would no doubt be forthcoming from among those who have already done highly creditable preliminary work, often under conditions of great disadvantage. When we consider that there are upward of seventy-five disorders peculiar to tropical climates treated at greater or less length in Manson's book on "Tropical Diseases," one is impressed with the growing importance of the entire subject.

This author writes further: "Although we do know something about a few of the tropical diseases and their germs, there must be many more tropical diseases and tropical disease germs about which we know absolutely nothing. Who can doubt that just as the fauna and flora of the tropical world are infinitely richer in species than those of colder climates, so there is a corresponding distribution in the wealth and poverty of pathogenic organisms; and that many, if not most, of the tropical diseases have yet to be differentiated."

Such an opinion expressed by one of the most ardent students of the subject must have weight. It is altogether fitting that America should take her place with England in these researches, and such an immediate opportunity seems to be offered in the Philippines. We hope the government may see fit to adopt the very modest recommendation made by Dr. Curry, and forthwith establish the nucleus, at least, of a school of tropical medicine at Manila.

MEDICAL NOTES.

TUBERCULOSIS IN CANADA. — Lord Minto, Governor General of Canada, has recently arranged a conference with reference to the checking of tuberculosis. It was declared the opinion of the conference that it is the duty of every government, municipality and individual citizen to adopt organized methods for lessening the spread of tuberculosis — a disease, it was stated, which was causing directly or indirectly probably one-fifth of the total deaths in the Dominion. The government was asked to assist.

ONE HUNDRED THOUSAND DOLLARS FOR TUBERCULOSIS HOSPITAL. — According to the *Medical Record*, on February 7th Senator Davis, of Buffalo, introduced in the Senate a bill appropriating $100,000 for the construction of buildings for the New York State Hospital for the treatment of incipient pulmonary tuberculosis. The buildings are to be large enough to accommodate at least 100 patients besides officers, employés and attendants. The additional sum of $20,000 is appropriated for equipment and furnishing.

SAMUEL D. GROSS PRIZE AGAIN NOT AWARDED. — No essay deemed worthy of this prize of $1,000 was awarded January 1st. It will be awarded October 1, 1901.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, February 20, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 105, scarlatina 31, measles 48, typhoid fever 4.

BOSTON MORTALITY STATISTICS. — The number of deaths reported to the Board of Health for the week ending February 16th was 243, as against 226 the corresponding week last year, showing an increase of 17 deaths, and making the death rate for the week 22.6. The deaths from consumption were 29, pneumonia 43, whooping cough 2, heart disease 25, bronchitis 6, marasmus 2. There were 19 deaths from violent causes. The number of children who died under one year was 37, under five years 69, persons more than sixty years 51, deaths in public institutions 69. There were 17 deaths from grip, but in 14 of these fatal cases other diseases contributed toward the cause of death.

A PLAN TO TAX BACHELORS. — As an inducement for young men to marry, a bill has been introduced in the House in Hartford, Conn., entitled "The Marriage of Bachelors." The bill reads as follows: "Every bachelor who shall remain unmarried at the age of forty years shall not thereafter be allowed to enter into any matrimonial alliance except upon the payment to the State of Connecticut of the sum of $100." The measure is said to be regarded seriously by its introducer.

BEQUEST TO PRESBYTERIAN HOSPITAL, NEW YORK. — By the will of J. Arent Vanderpoel, who died recently in Brookline, Mass., there is left, among other charitable bequests, the sum of $25.000 to the Presbyterian Hospital, of New York, to be available after the death of the testator's widow.

NEW ENGLAND BAPTIST HOSPITAL. — The New England Baptist Hospital has bought a piece of land on Mellen Street, Roxbury, where it already owns and occupies 35,862 square feet.

NEW YORK.

MORTALITY STATISTICS. — The Board of Health reports show a considerable increase in the mortality of the city in January over December, and over January of last year. The annual death rate in January, 1901, was 25.15, as against 20.73 in December, and 20.05 in January, 1900. The most marked increase is in the mortality from pneumonia, the weekly average of deaths from which was 270, against 175 in December. The weekly average of deaths from phthisis

increased from 148.25 to 179.75; influenza, from 5.75 to 88.75; diphtheria and croup, from 50.25 to 55.25; scarlet fever, from 5.75 to 18.50; bronchitis, from 35.50 to 54.75, and smallpox, from 1.25 to 2.25. The weekly average of deaths from typhoid fever decreased from 22.50 to 13.50; measles, from 4.25 to 1.75, and whooping cough, from 5.50 to 3.75. The highest mortality from pneumonia was reached in the week ending January 12th, when there were 328 deaths from the disease. It is probable that this fatality was largely due to the effect of influenza. In the week ending January 19th there were reported 139 deaths from influenza, independent of pneumonia.

THE NECESSITY OF A DIAGNOSIS QUESTIONED. — At the third hearing, on February 13th, before the Assembly Committee on Public Health, at Albany, on the Bell bill, the following somewhat extraordinary revelation was made by George Kinter, a "scientist healer." Being asked by Dr. Henry, chairman of the committee, what preparatory study the healers in Christian Science had, if any, he said that they took a course at the Massachusetts college of the society, and in reply to the question whether this course gave them the ability to diagnose disease, he stated that it did. Dr. Frank Van Fleet, of the New York County Medical Society, then put the question: "Would your treatment in a case of cerebral abscess, a fractured bone, a hemorrhage from an artery, or a case of smallpox differ?" "It would not," was the reply. "If your treatment never differs," asked one of the committee, "what is the necessity of your making a diagnosis." "Really, there is none," was the final answer.

ANNUAL REPORT OF GERMAN HOSPITAL AND DISPENSARY. — The thirty-first annual report of the German Hospital and Dispensary, just issued, shows that during the past year $10,047 was received in legacies and $4,964 in donations. Of 3,352 patients treated in the hospital department, 2,447 were free patients and the average daily cost of each patient was $1.20. An annex, with an accommodation of seventy beds, is now in course of construction, and it is expected will be completed by June. It is to cost $180,000, and of this amount $115,760 has thus far been collected among the German population of the city. The trustees report that, in order to meet the demands upon it, it has been found necessary to increase the number of pupils in the training school for nurses to fifty, and that a three years' course, which assures a higher degree of efficiency, has also been introduced.

THE BRAINS OF DR. EDOUARD AND DR. E. C. SEGUIN. — At a meeting of the New York Academy of Sciences held February 15th, Dr. E. A. Spitzka read a paper on the anatomical characteristics of the brains of the late Dr. Edouard Seguin and his son, Dr. Edward C. Seguin, which were bequeathed by these distinguished physicians to his father, Dr. Edward C. Spitzka. One of the most prominent features in both brains was the remarkable development of the left island of Reil, and it was noted that many peculiarities of the right side of the father's brain appeared on the opposite side of the son's brain. In closing, Dr. Spitzka urged all successful men to will their brains to science, since this important department of anatomical study is now confined, for the most part, to an examination of the brains of criminals and other outcasts of society.

LIBEL SUIT REGARDING LEPROSY. — In a libel suit tried in the Kings County Special Term, Justice Gaynor has held that to falsely publish of one that he has leprosy is libellous, since the disease, whether properly or not, is still commonly regarded as infectious or contagious, and as tending to cause the sufferer to be shunned or excluded from society. At the trial the defendant contended that it is now scientifically established that leprosy is not infectious or contagious, and therefore is no longer within the definition of slander.

NEW YORK ORTHOPEDIC DISPENSARY AND HOSPITAL. — According to the report of Dr. Russell A. Hibbs, surgeon to the hospital, during the year ending September 30, 1900, 164 patients were admitted to the wards, 110 discharged improved, 3 unimproved, 3 died and 48 remained under treatment October 1, 1900. The number of days of hospital care for free patients was 17,902; for pay patients, 2,894; total, 20,796. Thirty-six patients were treated by operative measures, and 57 operations were performed. All were successful.

BEQUESTS TO HOSPITALS. — Among the charitable bequests left by the late Oswald Ottendorfer, editor and proprietor of the *New Yorker Staats-Zeitung*, are $100,000 to the Isabella Heimath, founded by his wife, and $20,000 to the German Hospital and Dispensary. By the will of Mrs. Catharine Skatts, $5,000 is left to the New York Eye and Ear Infirmary, and $1,000 to the Home of St. Giles the Cripple, Brooklyn.

SMALLPOX. — On the arrival, on February 14th, of the Bremen steamship, *Oldenburgh*, which brought 1,132 steerage passengers, it was found that there was a case of smallpox on board, and the vessel was detained at quarantine until she could be disinfected and the passengers vaccinated. On February 11th there were 73 smallpox patients under treatment at the hospital for contagious diseases on North Brother Island.

NEW CONTAGIOUS PAVILION AT EYE AND EAR INFIRMARY. — The new Platt Pavilion, for the isolation and treatment of cases of contagious ophthalmia, has just been opened at the New York Eye and Ear Infirmary. The building was erected to the memory of the late James N. Platt, and presented to the institution.

ABOLITION OF PRESENT STATE BOARD OF HEALTH. — On February 14th, the State Senate passed a bill abolishing the present State Board of Health and establishing in its place a single-headed commission, in accordance with the recommendation of the governor in his annual message.

Obituary.

SAMUEL C. BUSEY, M.D.

SAMUEL C. BUSEY, M.D., died in Washington, D.C., February 12th, at the age of seventy-two. He was a member of the Association of American Physicians and of the American Pediatric Society. He had been for many years a prominent practitioner in the city of Washington, and was deservedly a highly respected man, of much influence both within and without the profession.

Correspondence.

NO PRACTICAL DANGER FROM THE X-RAY.

BOSTON, February 18, 1901.

MR. EDITOR: — In your issue of February 14th is published a letter from Dr. William Rollins, describing an experiment which, if confirmed by future observers, seems to me of very great importance. If the x-ray is capable of destroying life in the mammalia, the fact should certainly be brought to the attention of the medical profession. Dr. Rollins does not give the details of his experiment, merely his deductions. Other experimenters have found the x-ray incapable of destroying even the cryptogamic forms of organic life. However, I do not propose to contradict Dr. Rollins, and leave to the physicists and electricians the task of confirming or disproving the value of his experiments. Since Röntgen pointed out that non-conductors when traversed by the x-light may become conductors, the task of ruling out the electrical effect is not a light one.

What I do wish to call to the attention of your readers is this: that *practically*, in careful hands, there is no danger from the use of the x-ray *to the patient* and very little to the operator.

The facts on which I make this statement are these:

That in the last five years about 8,000 exposures in over 3,000 cases have been made at the Massachusetts General Hospital *without a single case of x-ray dermatitis in the patient.*

That at the Children's Hospital, in the last eighteen months, we have made about 1,000 exposures in over 300 cases, without a *single case of dermatitis in the patient.*

That in the last five years, in my private practice, I have made nearly 1,000 exposures without a single case of dermatitis in the patient.

The sum total is about 10,000 exposures in 4,000 cases without one case of loss of hair or burn of the skin.

As far as danger to the operator goes, there is no question that a serious dermatitis extending into the deeper layers may be set up. At times my own hands have had the typical appearances of a slight grade of this form of burn, but they have never been excoriated nor cracked, nor so severe that I could not go through the ordinary permanganate preparation for surgical operations. I attribute this freedom from trouble to my habit of never exposing myself near the tube if I can possibly help it. I take no other precautions. One severe case of maiming dermatitis I have seen, in a gentlemen whose enthusiasm outweighed his prudence, but the value of whose work has almost compensated for the sacrifice.

I seek the opportunity of mentioning these facts in your columns because I believe that the comparatively small number of unfortunate cases which have been published have circulated much farther than the immense number of fortunate cases, and have given the profession the idea that the process is a dangerous one *to the patient.* No doubt Dr. Rollins's precautions are necessary to an operator who constantly uses this form of diagnosis, but my personal experience leads me to think that the important point is to keep the hands away from the tube. Such sensational headings as "X-Light Kills" are apt to give a wrong impression. The fact that the x-ray is in daily use in the large hospitals without harmful results should be put in blacker type than the death of two guinea pigs.

Very truly yours,

E. A. CODMAN, M.D.,

Surgeon to Out Patients, Massachusetts General Hospital; Skiagrapher to the Children's Hospital.

METEOROLOGICAL RECORD

For the week ending February 9th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Deaths reported 2,399; under five years of age 604; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping cough,

erysipelas, fevers and consumption) 520, acute lung diseases 402, consumption 280, diphtheria and croup 73, diarrheal diseases 48, scarlet fever 43, influenza 37, typhoid fever 22, whooping cough 11, cerebrospinal meningitis 6, measles 5.

From whooping cough New York 3, Baltimore and Cambridge 2 each, Providence, Pittsburg, Boston and Everett 1 each. From cerebrospinal meningitis New York 5, Boston 1. From scarlet fever New York 30, Malden 4, Worcester 3, Pittsburg and Somerville 2 each, Boston and Revere 1 each. From typhoid fever New York 9, Pittsburg 6, Worcester 2, Baltimore, Boston, Somerville, Salem and Taunton 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,789,099, for the week ending January 26th, the death rate was 17.9. Deaths reported 4,039: acute diseases of the respiratory organs (London) 394, whooping cough 92, diphtheria 75, measles 58, fever 48, diarrhea 43, scarlet fever 31.

The death rates ranged from 10.5 in Portsmouth to 24.6 in Gateshead: Birmingham 20.4, Brighton 17.5, Bristol 14.1, Croydon 13.2, Derby 15.2, Halifax 19.5, Hull 18.9, Leeds 17.3, Liverpool 24.0, London 17.6, Manchester 20.2, Newcastle-on-Tyne 20.4, Norwich 23.7, Nottingham 19.5, Plymouth 19.1, Sheffield 19.7, Swansea 16.0, West Ham 11.6.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING FEBRUARY 16, 1901.

C. P. BAGG, passed assistant surgeon, detached from Cavite Naval Station and ordered to the "Culgoa," February 7th.

A. R. ALFRED, passed assistant surgeon, detached from the "Culgoa" and to the Naval Station, Cavite.

C. BIDDLE, surgeon, detached from the Naval Hospital, Norfolk, Va., and ordered home to wait orders, February 9th.

D. O. LEWIS, surgeon, detached from the "Iowa" and ordered to the "Philadelphia," February 13th.

W. F. ARNOLD, surgeon, detached from the Naval Recruiting Rendezvous, Chicago, Ill., March 1st, and to the "New Orleans," sailing March 15th.

S. H. GRIFFITH, surgeon, detached from the "Prairie," when put out of commission, and ordered to special duty under the Bureau of Medicine and Surgery.

F. J. B. CORDEIRO, surgeon, detached from the "New Orleans," on reporting of relief, and home to wait orders.

A. M. MOORE, surgeon, retired, ordered to duty at the Naval Recruiting Rendezvous, Chicago, Ill., March 1st.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING FEBRUARY 14, 1901.

SAWTELLE, H. W., surgeon. Granted leave of absence for thirty days from February 20th. February 14, 1901.

KALLOCH, P. C., surgeon. Granted leave of absence for three days from February 17th. February 8, 1901.

GEDDINGS, H. D., passed assistant surgeon. Granted leave of absence on account of sickness, for eight days, from January 26th. February 12, 1901. Granted leave of absence for thirty days from February 3d. February 12, 1901.

GARDNER, C. H., passed assistant surgeon. Granted leave of absence for seven days. February 11, 1901.

PARKER, H. B., assistant surgeon. To proceed to Gulf Quarantine and assume temporary command of the service during the absence on leave of the medical officer. February 8, 1901.

MOORE, DUNLOP, assistant surgeon. To proceed to Port Townsend, Washington, and assume temporary command of the service during the absence on leave of the medical officer in command. February 11, 1901.

MCCOY, G. W., assistant surgeon. Granted leave of absence for fourteen days from March 18th. February 12, 1901.

SOCIETY NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY.— The Section for Obstetrics and Diseases of Women will meet in Sprague Hall, Boston Medical Library Building, 8 The Fenway, Wednesday, February 27, 1901, at 8 P. M.

Papers: Dr. Edward B. Lane, "Puerperal Insanity."

Dr. William J. Daly: "Ophthalmia Neonatorum."

Dr. Sarah Palmer: "Hysterectomy for Rapidly Growing Myoma, Complicated by Pregnancy."

E. S. BOLAND, M.D., *Chairman.*

W. H. GRANT, M.D., *Secretary*, 419 Boylston Street.

THE NEW ENGLAND HOSPITAL MEDICAL SOCIETY.—A regular meeting of the society will be held at 3 Park Street, on Thursday, February 21st, at 7.30 P. M.

Papers: "Cesarean Section and Hysterectomy for Fibroid Uterus," by Dr. Mary A. Smith.

"Mental Defectives: Their Needs," by Dr. Bertha C. Downing.

AGNES C. VIETOR, M.D., *Secretary*, Trinity Court.

THE PHILADELPHIA NEUROLOGICAL SOCIETY. — A stated meeting of the society will be held on Monday, February 25, 1901, at 8.15 P. M.

Drs. Wm. H. Teller and F. X. Dercum will exhibit "A Case of Astereognosis."

Drs. George L. Walton and Walter E. Paul, of Boston, will, by invitation, read a paper entitled "Astereognosis: with Illustrative Cases."

AUGUSTUS A ESHNER, M.D., *Secretary.*

WESTERN OPHTHALMOLOGIC AND OTO-LARYNGOLOGIC ASSOCIATION. – The association will meet in its next annual session in Cincinnati, O., April 11th and 12th.

W. L. BALLENGER, M.D., *Secretary.*

APPOINTMENTS.

F. W. SPALDING, M.D., has been appointed visiting ophthalmologist to the Long Island Hospital, Boston Harbor.

JOHN J. MAGRATH, M.D., has been appointed attending surgeon to the Harlem, N. Y., Hospital.

ERRATUM.

In a note on *Diphtheria at the Naval Hospital, Chelsea*, published in the issue of the JOURNAL for February 7th, an error was made in the text, in the substitution of "marine" for "naval." The sentence should read: About 30 cases of mild diphtheria have developed at the *Naval* Hospital in Chelsea.

RECENT DEATHS.

BENJAMIN FRANKLIN, M.D., of Newark, N. J., died from the effects of influenza on February 6th, at the age of fifty-four. He was born in New York and graduated from the Medical Department of the University of the City of New York, and was a veteran of the Civil War.

FRANK BOND, M.D., of Brooklyn, N. Y., died on February 10th. He was born in Erie County, Pa., in 1827. He was graduated from Williams College in 1851, and from the Medical Department of the University of the City of New York in 1857.

PETER MOIR BARCLAY, M.D., a leading physician of Orange County, N. Y., died at Newburgh-on-the-Hudson, on February 11th. He was born in Aberdeen, Scotland, in 1834, and was graduated from the Medical Department of the University of the City of New York in 1855.

BOOKS AND PAMPHLETS RECEIVED.

A Clinical Case. By A. R. Moulton, M.D. Reprint. 1900.

Report of the Commissioner of Education for the Year 1898-99. Vol. II. Washington. 1900.

Annual Reports of the President and the Treasurer of Harvard College, 1899-1900. Cambridge. 1901.

Transactions of the Luzerne County Medical Society for the Year ending December 31, 1900. Vol. VIII.

The Johns Hopkins Hospital Reports. Vol. VIII, Nos. 3-9. Baltimore: The Johns Hopkins Press. 1900.

Fifteenth Annual Report of the State Board of Health and Vital Statistics of the Commonwealth of Pennsylvania. Vols. I and II. 1899

A Clinical Treatise on Fractures. By William Barton Hopkins, M.D., Surgeon to the Pennsylvania Hospital, etc. Philadelphia: J. B. Lippincott Co. 1900.

Massage, Movements and Bandaging in the Treatment of Displaced Semilunar Cartilages. By Douglas Graham, M.D., Boston, Mass. Reprint. 1896.

Double Ureter; Report of a Nephrectomy done upon a Young Child with this Condition Present. By John Edward Summers, Jr., M.D., Omaha, Neb. Reprint. 1901.

Report of the Connecticut Hospital for the Insane to the Governor for the Two Years ended September 30, 1900. Middletown, Conn.: Printed by order of the Legislature. 1900.

Obstetric and Gynecologic Nursing. By Edward P. Davis, A.M., M.D., Professor of Obstetrics, Jefferson Medical College, etc. Philadelphia and London: W. B. Saunders & Co. 1901.

Reports of the Trustees and Superintendent of the Butler Hospital for the Insane, presented to the Corporation at its Fifty-seventh Annual Meeting, January 23, 1901. Providence, R. I.

Sixteenth Report (Third Biennial) of the State Board of Health of the State of New Hampshire, for the Two Years Ending November 1, 1900. Manchester: Arthur E. Clarke. 1901.

The Use of the Röntgen Ray by the Medical Department of the United States Army in the War with Spain (1898). Prepared under the direction of Surgeon-General George M. Sternberg, U. S. A. By W. C. Borden, Captain and Assistant Surgeon, U. S. A. Washington. 1900.

Original Articles.

THE USE AND ABUSE OF SPECTACLES.

BY HASKET DERBY, M.D., BOSTON.

Within the memory of living practitioners the choice of spectacles was made by the patient needing them, either on his own responsibility or aided by the optician of whom they were purchased. It was not until 1858 that Donders wrote his first article, entitled "Hints relating to the Use and Choice of Spectacles," and published it in Graefe's *Archive*. For several years following the illustrious professor of Utrecht continued to write on the same subject, and finally, at the instance of the New Sydenham Society, he brought out, under its auspices and in the English language, his great work on "The Anomalies of the Accommodation and Refraction of the Eye."

The introduction of the new doctrines and the placing the choice of glasses in the hands of the ophthalmic surgeon followed in our own country somewhat slowly. In 1861 the Eye Infirmary in this city possessed no trial case of glasses, a few battered frames containing glasses of high power for the use of patients who had been operated on for cataract comprising its entire resources in this line. And in 1862 a leading American ophthalmic surgeon wrote thus: "When possible, any one desiring glasses should go in person to select them from the establishment of a good optician."

With the return from Europe of the younger men of this day, a different system soon began to prevail. The prescription of glasses was now recognized to be properly within the province of the surgeon, and in his hands it has by right ever since remained. In the beginning his task was a simple one. Near sight and old sight, myopia and presbyopia, had been the only conditions recognized by the public at large as requiring the use of glasses. Hypermetropia now first came into prominence as a common form of refractive error, and its neutralization greatly increased the number of glasses worn in the community. Astigmatism was still comparatively unknown. Discovered and described as it existed in their own eyes by Thomas Young in 1793, and later by the astronomer Airy in 1836, the condition was long regarded as an anomaly of infrequent occurrence. Donders published his monograph on this subject in 1862. At this time no trial case, even though made in Germany, contained any cylindrical glasses. The first pair ordered in Boston were prescribed in 1863. The order had to be sent abroad to be filled, and the patient himself walks our streets today. Muscular asthenopia, first brought forward by Graefe in 1862, and with its domain much widened by the researches of Stevens, of New York, has rendered the prescription of prismatic glasses, either alone or in combination, quite a frequent occurrence. The busy practitioner of today finds it hard to imagine the comparatively small number of prescriptions for glasses but little more than forty years ago.

It would be well if this matter of ordering glasses had remained in the hands of the educated physician. But with the increase in the number of recognized anomalies of refraction, opticians themselves multiplied. Optical institutes became the fashion, and proffered instruction on easy terms and extending over but a brief period, in some cases offering to teach by correspondence, to examine candidates for degrees in the same manner, and then to forward the degree itself on the receipt of a stipulated sum. A little knowledge soon proved a dangerous thing. The shop windows in our principal streets teemed with placards, announcing that eyes were examined free of charge; while the rural districts were soon raided by peripatetic sellers of spectacles, who furnished ill-fitting and worse made glasses at a heavy cost, professing to hail from some well-known institution or infirmary, or giving some other false address.

The prescribing of glasses by incompetent and often unprincipled individuals is an abuse that cannot easily be corrected. To the honor of the better class of opticians in a city like our own be it said that they prefer to fill orders sent them, and as a rule avoid the selection of glasses on their own responsibility. If the case be a complicated one, or if the lenses previously worn have been ordered by a surgeon, they refuse to prescribe or change, and urge the patient to seek professional advice. More could not be asked of them, for they naturally cannot be expected to turn away customers who are willing to bear the burden of making their own selections.

Ordered, then, authoritatively or carelessly, the use of spectacles has enormously increased within the past generation. One may walk the streets of Boston and almost fancy himself in some city of Germany or Russia, so numerous are the wearers of glasses. Particularly is this to be observed among young children, both here and abroad. The German writer Seidel has written a little poem in which he pictures two old people sitting together and discoursing about the good old times of their youth, when the world wore so different an aspect. They enumerate many things that were better in those days. And at last one says:

> "The children then were not so pert,
> No spectacles they wore." [1]

The attention of the laity has therefore also been attracted to this state of things.

It is of but little use to allude to the mistakes made by ignorant opticians, or the impositions practised on the public by those greedy of gain. The writer has recently seen a case of simple hypermetropia set down as one of compound astigmatism, and a correspondingly complicated and costly glass ordered; he has seen prisms given where there was no muscular weakness, and cylindrical lenses furnished in emmetropia. He has known a presbyopic patient, suffering from tobacco amblyopia, to be provided with a weak concave lens for reading purposes. The tendency to swell the profits of the store by the sale of a compound glass at a high price is to a certain class of dealers irresistible. Such conduct on the part of opticians it is easier to deplore than to prevent.

But how is it with ourselves? Does the ophthalmic surgeon of the day make no mistake? Do we not, with the best intentions, occasionally order glasses in cases where their use is not strictly needed, and by enjoining their habitual employment create a dependence on artificial aid that ultimately grows into a necessity? Do we sufficiently consider the moral effect on children, the ridicule the boy or girl at first experiences from his or her companions; the consequent effect on many a sensitive nature; the cosmetic

[1] "Die Kinder waren nicht so keck,
Sie trugen keine Brillen."

disadvantages in the case of young and growing girls; the possible handicap of the young man in search of employment? These considerations are adduced, not that they should be allowed to interfere with needed assistance to refraction, but that they may be at least given due weight in doubtful cases.

Giving his personal opinion for what it is worth the writer's experience has occasionally led him to differ from some of his colleagues in the ordering of glasses.

Before alluding to the different forms of ametropia in which lenses are prescribed, it is well to consider a single source of error on the part of the patient, namely, the influence of the imagination. Great as are the advantages gained by the objective methods of examination, by ophthalmometry, ophthalmoscopy and skiascopy, it is, I think, a recognized fact that it is ordinarily undesirable to base a prescription for glasses solely on the above tests. The patient himself must be questioned and his judgment appealed to. The vision of the unaided eye is, for instance, found to fall slightly short of the normal standard; a weak convex or concave lens, spherical or cylindrical, restores normal vision. Let it not, however, be inferred that the patient, if a young person, surely needs this glass. What examiner has not seen the vision instantly raised one or two-tenths by the application of a pair of plane spectacles? I always test a child with a heavy empty frame, observing its effect, and I often find some improvement in sight. This test occasionally is found of value with those of riper years. The explanation would seem to be simple; the weight of the apparatus induces a belief in its complexity, the patient feels that some change in his sight ought to follow, makes an additional effort and often really sees more in consequence. Occasionally, however, he has heard of the application of this test in others, and comes prepared for it. If I observe him to be suspicious I use with him a pair of glasses the outer surface of which is convex 1 D., and convince him of this fact by the application of the lens measure, the principle of which I manage to explain. If, with these glasses, he sees better, the imagination is again a factor, for I have omitted to inform him that the posterior face of the glass is just as concave as the anterior is convex, and that he is really wearing a pair of plane glasses. If, then, vision remains the same, we are dealing with one whose judgment may be relied on.

There are many who in hypermetropia advise the constant use of neutralizing glasses, both by old and young, and many patients who obey this direction. In this we have departed from the advice Donders originally gave. Speaking of those who in the ordinary affairs of life suffer no inconvenience, and at a distance see well, he says, "We should not press spectacles on them to be worn constantly."[2] This teaching has been confirmed by the most reliable authors, although here and there a writer of eminence takes the opposite view. It would seem that the advice occasionally given those moderately hypermetropic, to put on their glasses on rising and remove them only on retiring, is in many cases injudicious. The patient has become habituated to the moderate use of his accommodation on distant objects, and suffers no ill effects from the slight strain. He sees clearly and distinctly. The use of glasses for the street enfeebles the accommodation, which after they have been worn any length of time rarely regains its former power. The patient is reduced to a dependence upon them which might otherwise have been avoided. It is perhaps imperative that they be used for near work, but when asthenopic symptoms are at other times wanting I believe it to be a serious error to insist on their constant employment. And if the refractive error be not excessive I always attempt to emancipate the patient from his street glasses.

Myopia. — It is in the ordering of glasses for those who are near sighted that the optician makes his most fatal errors. Possessed of no useful knowledge of the ophthalmoscope, and unable to appreciate the existence of serious and possibly progressive organic change in the eye itself, one case of myopia is to him the same as another, and he prescribes the glass that gives the greatest visual acuteness. It is not until incurable macular changes or retinal separation have driven the patient to seek proper medical advice that he realizes how disastrous has been his policy in accepting glasses from unprofessional hands. It may be laid down as an axiom that no glass should be ordered in myopia until a thorough investigation of the history of the patient, the family tendencies, the acuteness of vision and the condition of the interior of the eye has been made. Moreover the case should be carefully followed up from year to year, and the progressive or non-progressive character of the disease fully determined. It is not too much to say that all children should be examined at least once a year during their school life, in order that the first invasion of near sight may be detected and promptly encountered. Fortunately the tests for this purpose are so simple and so readily accessible that the simple examination of the condition of vision may, under ordinary circumstances, be safely conducted by the parent or teacher.

And as we are now treating of the use as well as the abuse of spectacles, it is well to here allude to the important part glasses play in checking the progress of myopia in the young, more especially as so little is to be found on this subject in the accepted textbooks. Donders distinctly advised against the use of glasses for near work in slight degrees of myopia, as well as against full neutralization in the young, at any rate when glasses were first used. He quotes cases of considerable and advancing myopia with good acuteness of vision, treated by rest of the eyes and relatively weak glasses, the trouble, however, still progressing. Other writers have followed his teachings, and we find one of the most careful and reliable of modern teachers, Professor Fuchs, of Vienna, whose book more than any other is probably held at the present day to be the standard manual of opthalmology, saying nothing in his edition of 1898 in regard to the use of neutralizing glasses for all purposes in cases of progressive myopia in the young. When the myopia is 2 D. or less he distinctly advises against the use of glasses for the near, and makes no allusion to the possible prevention of the increase of the near sight.

The credit of devising the most efficacious means for this purpose belongs certainly to American ophthalmologists. At the twenty-eighth annual meeting of the American Ophthalmological Society, in 1892, Dr. Jackson, of Philadelphia, read a paper on the "Full Correction of Myopia," and Dr. Harlan, of

[2] Accommodation and Refraction of the Eye, 1864, p. 281.

the same place, on the "Constant Correction of High Myopia." They both opposed the teaching of Landolt, who states in his work on "The Accommodation and Refraction of the Eye" (English edition, page 490), that "a myope must be prohibited from wearing a concave glass for any distance in which he can clearly see without accommodation." They both advocated the constant and full correction of myopia, especially in the young, as a means of preventing its progress. The discussion that followed the reading of these papers showed substantial unanimity on the part of the members present in approving the views of the readers.

It would be difficult to overestimate the importance of this discovery, for a discovery it is in the true sense of the word. Its general acceptance, in this country at least, at the present day has proved of great advantage. A young person, at the age of twelve or fourteen, begins to complain that he cannot see the blackboard across the schoolroom as well as formerly. Examination shows a moderate myopia, .75 D. or even 1 D. Six months later this has increased to perhaps 1.5 D. Glasses of this strength are given and their constant use enjoined. The progress of the near sight is probably at once arrested, or in the majority of cases its subsequent increase is found to be relatively slight. Certain cases in my own practice have made a deep impression on me. One of these, a boy of ten, came to me many years ago for some slight inflammatory trouble. I took occasion to examine the sight, knowing that both father and mother were very myopic, and found the refraction and vision alike normal. Two years later very slight myopia, about .25 D., was present. This steadily increased, and in seven years had become 5 D. Since then it has, I think, remained stationary. This was some time before the publication of the observations of Jackson and Harlan. Another case is that of a young girl of eight who had normal eyes. At the age of nine she had a myopia of 1.25 D. She went several times through the atropine treatment, with the result of temporarily arresting the progress of the near sight. At thirteen she had myopia 2.75 D., at fourteen, 3.5 D., despite much rest of the eyes and frequent courses of atropine. At fifteen there was myopia 4 D. I had just learned the advantages of full neutralization, and now for the first time gave her the necessary glass. Seven years have now elapsed, and there has been no further progress. Another case was that of a lad, who in 1890, at the age of ten, was slightly hypermetropic. In 1894 he had myopia .5 D. He now went through the atropine treatment without result. There was myopia 1 D. in 1895. He was given neutralizing glasses in 1896, and in 1898 his myopia was found to be stationary. He has since left off his glasses, and although he has since worked hard at the study of civil engineering there has been no change for the worse. These cases are quoted for the purpose of illustration.

Thus in hypermetropia we see glasses worn too much, in myopia probably too little. In speaking of astigmatism we open a new chapter. So much relief has been given to many reflex disturbances by the skilled adaptation of cylindrical glasses, so many headaches have been cured, and so much asthenopia prevented by their use, that they have been and are frequently prescribed in cases where they are not strictly needed, and we find glasses that either do no good or even inflict a certain amount of injury worn by many today. Leaving out of the question the needlessly complicated and costly lenses prescribed by ignorant or rapacious opticians, it is sometimes a question whether we ourselves do not occasionally stray from the path of simplicity, whether we do not rely too exclusively on the objective methods of examination and endeavor to neutralize the astigmatism obtained by the ophthalmoscope, the ophthalmometer, the shadow test, and even subjectively by the patient's inspection of the radiating lines on the astigmatic test card, rather than the simple test of vision on the letters of Snellen or Monoyer. My own experience certainly is that where vision in each eye is normal, whether without glasses or by the aid of the ordinary sphericals, there is little to be gained by going into the question of the existence of slight degrees of astigmatism. "*Das Bessere ist der Feind des Guten*," as the proverb has it. I make this statement with diffidence, well aware that many whose opinions are entitled to respect will not agree with me. It is becoming unusual for patients who already wear glasses to bring in simple lenses for inspection and possible change, so great is the professional tendency to prefer complexity. I certainly believe that a cylindrical addition may safely be dispensed with in cases where vision, either with or without a spherical glass, is found equal to unity.

Concerning the use of prisms there is less to be said. Muscular weaknesses receive local treatment much less frequently than was the case a few years ago. The day has largely gone by when a series of so-called partial tenotomies would be performed, not only for the relief of asthenopia, but even of serious general disease, such as epilepsy and chorea. It is true that this method of treatment has its sphere of action, but a more limited one than was formerly supposed. The writer has come across people whose ocular muscles have been operated on, not only for the relief of headache, but for the cure of rheumatism of the shoulder and torpidity of the bowels. The numerous cases of distressing diplopia and artificial insufficiency that have resulted from the too exclusive use of such a surgical method have brought about its partial abandonment, and this has led to a decrease in the number of prismatic glasses formerly prescribed. It is more and more frequently found to be the fact that apparent muscular anomalies vary directly with the condition of the general health. Within a month or two the writer has seen the entire disappearance of a hyperphoria for which a prismatic glass had been worn two years with great relief, and has verified the restoration to the normal condition of an excessive exophoria on which, in years gone by, he had vainly urged an operation, and for which heavy prisms had been prescribed and worn with much temporary advantage.

AVULSION OF THE FINGER, WITH A CASE IN WHICH THIS ACCIDENT OCCURRED TO AN INFANT TWENTY MONTHS OLD.

BY GEORGE H. MONKS, M.D., BOSTON.

On November 24th I saw with Dr. Bernard T. Daly, of Roxbury, the following case, which seems to me of such unusual nature as to justify its publication.

It appears that an infant, a girl of twenty months, was crawling about the floor, and in some way inserted the little finger of her right hand into the jamb of a door. Immediately after this the door was closed. The parents realized at once that some accident had happened, but they did not discover that the child was definitely injured until, on looking at the right hand they saw that the little finger was missing, a bloody stump appearing in its place. A search was made for the finger, and it was found in the jamb of the door where it had been caught (Fig. 1). The child was given ether, and the stump was trimmed up. In order to get skin enough for the flaps it was found to be necessary to dissect out the first phalangeal bone, which still remained connected with the hand. The flaps were then united by suture. Recovery followed.

An examination of the finger, which was somewhat dried when I saw it, showed that a long portion of the flexor tendon was attached to it — a fact which suggested that the finger had not been simply crushed off, but actually torn off by traction of some sort. Exactly

FIG. 1.

how the traction was applied is not clear. The history throws no light on it. It is quite possible that, at the moment the finger was caught, the child herself instinctively pulled back her hand with such force away from the finger, as it were, that the finger and the tendon were left in the door.

This injury is commonly referred to in the textbooks, and occasionally cuts illustrate the text. An illustration in Billroth shows a middle finger, which has been torn from the hand. Attached to the finger are two flexor tendons and one extensor. Beside this cut is another showing the entire arm, including scapula and clavicle, which had been pulled off by machinery. In Bryant's "Surgery" there is an excellent drawing of an avulsed finger. In the first volume of Dennis's "Surgery" are beautifully shown several terminal phalanges of the thumb which had been torn off in various ways — one of them in an attempt to reduce a thumb dislocation. A flexor tendon is attached to each specimen.

In the Warren Museum at the Harvard Medical School there are several interesting specimens illustrating avulsion, to which the curator, Dr. Whitney, kindly called my attention. Among them are the following:

No. 1,619. A dry specimen furnished by Dr. H. O. Martin, of Roxbury, in 1854. In this case the last phalanx of the thumb was torn off, and the whole of the long flexor drawn out.

No. 1,621. Specimen, sent by Dr. King, of Nantucket, in 1856, consisting of the last phalanx of the little finger and about 10 inches of the flexor tendon. The finger had been amputated at the joint by a finger ring. The specimen — so the story goes — was from a man who, in falling from the upper deck of a steamboat, caught his finger ring upon a hook, where it was left hanging with the finger and tendon.

No. 3,723. Specimen showing two phalanges of the index finger torn off at the articulation by machinery, and 7½ inches of the flexor tendon drawn out. (Dr. H. J. Bigelow in 1870.)

No. 5,307. Middle finger of right hand torn off by machinery and flexor tendon with shreds of muscle drawn out. (Dr. John Jeffries in 1843.)

No. 5,308. A dried specimen. The last joint of the index finger torn off, and with it the flexor tendon, and a small piece of muscle. "The patient, a healthy lad of seventeen years of age, got his finger caught beneath a heavy piece of timber, and without waiting for assistance, made a sudden and strong effort, and tore it off at once." (Dr. James B. Gregerson.)

No. 5,411. "The skin and nail of the little finger from a lad of thirteen years, who, jumping up to reach something on a hook, got the hook caught in a ring which he had upon the finger, and tore the skin and nail entirely off. The patient eventually had a serviceable finger, upon which a rudimentary nail grew. The ring accompanies the specimen."[1] (Dr. William E. Coale in 1845.)

No. 6,312. The specimen consists of the last phalanx and the skin that covered the last two phalanges in connection with it. The patient, a young clerk in the post office, who had a thin plain gold ring upon the little finger of his right hand, slipped from a stool, the ring catching in a hook as he fell. This ring, cutting through the skin on the back of the finger commencing just below the second joint, amputated the last phalanx at the joint. The ring remained on the hook and the finger fell to the floor. There was very little hemorrhage.[2] (Specimens furnished by Dr. D. S. Slade. Case reported in the *Boston Medical and Surgical Journal* for February 8, 1855.)

No. 6,577. "The little finger and flexor tendon torn off by a finger ring. From a young man who jumped from the top of a stage coach and caught the ring in the rail." The integument is extensively lacerated, and the last phalanx completely separated from the second at the articulation; but flexor tendon not torn through at this point. The accident happened in July, 1866.

Another specimen, a dried one, consists of the principal part of the right hand with a thumb and three fingers. Many long tendons are attached. The ap-

[1] No bone was torn off in this instance. It is the only case I could find where all the soft parts, including the nail, had been pulled off, the bones and tendons remaining with the rest of the hand.

[2] It is worthy of note that no tendon was pulled out in this case, all the tendons having been severed at about the level where the finger was torn off.

pearance of the specimen suggests avulsion. No history can be found.

In the "Museum Catalogue," under the heading of No. 3,709, a case is related in which the entire upper extremity of a boy of thirteen years was torn off as a result of its being caught in a machinery belt. This patient survived the terrible injury. Three photographs can be seen at the museum, showing his condition after recovery. The case occurred in the practice of Dr. Charles D. Homans. The accident happened in 1870.

But, returning to the subject of avulsion of the fingers, the following *general observations* may be made:

(1) *As to the nature of the accident.* — (*a*) The finger may be firmly held in something moving away from the person with considerable force, as machinery, vehicles, etc. The tearing off of a terminal phalanx in efforts to reduce a dislocated thumb would thus come under this heading. (*b*) The finger may be held while the body, or at least the hand, is pulled away from it. Thus, the finger may be caught on a hook or any other projecting object, while the person is rapidly moving, as in jumping, falling or running. A finger ring catching on such a projection amputated the finger in a number of cases given. It is likely that the involuntary "pull-back" of a hand, one finger of which has been suddenly caught, as in the case of the infant described at the beginning of this article, may be in certain cases of sufficient force to pull the hand away from the finger.

(2) *As to where the bones usually give way.* — The joints are the weakest parts, and, therefore, it is usually at a joint that the phalanges are separated from the rest of the hand. Avulsion of the terminal phalanx would appear to be the commonest variety. Occasionally, when the finger has been much crushed or bent, a phalanx may break and the joint may hold. The separation rarely takes place as far back as the metacarpophalangeal joint.

(3) *As to whether or not the tendon is pulled out.* — A tendon — and it is generally the deep flexor tendon — is usually attached to the avulsed finger and forms part of the specimen. Sometimes both flexors and the extensor come away with the finger. The finger has been known to come off without either tendon; a circumstance which suggests that the violence in this special case was quite as much in the nature of a crush as a pull. The end of an avulsed tendon usually exhibits a few muscular shreds, suggesting that the rupture took place at the spot where the tendon was entering the muscle. This spot would therefore seem to be the weakest point. The reason that the deep flexor is usually found attached to the avulsed finger is (*a*) because this tendon is a round cord (not flattened nor split like the others), and is probably the strongest of all the tendons; (*b*) because it is attached to the base of the terminal phalanx, and therefore in all cases it is pulled upon.

(4) *As to where the skin and other soft parts are torn off.* — In almost all cases the skin is torn from the finger at a much higher level than that where the bones give way. If the violence of the pull has been more or less superficial, it may happen that only the skin and soft parts are torn off, the bones and tendons remaining connected with the hand.

(5) *As to hemorrhage.* — It would appear that the bleeding following the accident is seldom troublesome. This is just what one would expect, as tearing a blood vessel probably favors contraction of the torn ends just as twisting does.

(6) *As to treatment and result.* — In order to get flaps it will always be necessary in cases of this kind to dissect out a portion of the bone in the stump. The operation is very simple, and the results, even in the days before the use of aseptic or even antiseptic methods, were almost always good, so far as healing was concerned. This is rather singular, as in former times such a wound was pretty sure to be infected, and the long synovial track left empty by avulsion of the tendon invited an extension of the suppurative process up the arm.

No attempt should, of course, be made to replace the avulsed portion of the finger, as has been sometimes done with severed digits. An injury of this nature has damaged the part beyond possibility of repair.

TWO CASES OF LIGATURE OF THE INTERNAL JUGULAR VEIN FOR INFECTIVE THROMBOSIS OF THE SIGMOID SINUS DUE TO PURULENT OTITIS MEDIA; ONE RECOVERY AND ONE DEATH.[1]

BY FREDERICK L. JACK, M.D., BOSTON.

LIGATING the internal jugular vein as a preliminary to operating for sinus thrombosis is comparatively rare. We know from the data already at hand that the mortality in sinus thrombosis has been less in those cases in which the vein has been ligated. The records of many cases must be accumulated, however, before such comparisons are of value. These 2 cases are reported with a view of adding to the statistics bearing on this point, as well as with the hope that they may throw some light on the subject in general.

CASE I. P. L., a man of thirty-four, was admitted to the Massachusetts Charitable Eye and Ear Infirmary, Boston, August 30, 1900. He was suffering from a suppurative right middle-ear inflammation of two months' standing. He had always been in good health up to this time. Since the beginning of the attack he had had otorrhea, pain in the ear and right side of the head, varying in intensity. On admission the auditory canal was found filled with a purulent discharge; the inner posterior wall was bulging. The membrana tympani was of dark color and boggy, and there was a small perforation in the posterior inferior quadrant. The mastoid process was tender to deep pressure, especially over the tip. The patient remained fairly well for five days, when the temperature rose to 101° F., with a chill. Examination of the eyes was negative. The blood count was normal.

Operation. — On September 5th the mastoid antrum and the middle ear were opened in the usual way, and found filled with pus and granulation tissue. The bone over the sigmoid sinus was removed with chisel and mallet, exposing the wall of the sinus for ¾ inch. The wall of the sinus was carefully examined and found thickened and covered with granulation tissue. The granulations were removed and the wound was thoroughly irrigated and dressed with iodoform gauze. The next morning a severe chill

[1] Read by title at the Third Pan-American Medical Congress, Havana, February 4, 1901.

occurred, a rise of temperature to 102° F., followed by profuse perspiration. The pulse was 130. Upon changing the dressing the exposed wall of the sinus appeared very dark in color without pulsation. It was evident that the sinus contained a disintegrating thrombus and its removal after ligating the internal jugular was deemed the safest means of arresting further septic absorption. An incision 1 inch below the tip of the mastoid along the anterior border of the sternocleido muscle was made. Dissection was carefully continued down to the large vessels in the neck and the vein separated from the sheath. An aneurism needle was then passed under the vein above the anterior belly of the omohyoid muscle and the vessel ligated with catgut. The incision was closed with silk sutures. The sigmoid was then opened and a small thrombus containing pus was removed. The wound was thoroughly cleansed and lightly packed with iodoform gauze. For three days following the operation, the symptoms improved and the temperature remained normal. The wound in the neck healed by first intention and the stitches were removed. On the fourth day, however, the patient complained of a chilly sensation and temperature rose to 101° F. There was slight discharge of pus from the mastoid wound. During the next two days there were two chills with subsequent elevation of temperature from 104° to 101° F. The mastoid wound was frequently dressed and thoroughly cleansed. The blood count again was negative. The urine was normal. Seven days after the operation a lull took place in the symptoms and the temperature dropped to 95° F. This subnormal temperature persisted for several days.

From now on the patient made an uninterrupted recovery and was discharged from the infirmary thirty days after ligating the internal jugular vein. Both wounds were perfectly healed.

CASE II. P. K., male, twenty-two years old, admitted to the infirmary September 19, 1900, suffering from a chronic otorrhea in the left middle ear with an infective sigmoid sinus thrombosis and probable cerebral abscess. The discharge from the ear had been constant for several years. His present illness dated back six days prior to his admission, when he complained of intense pain over the left side of the head followed by vomiting and rigors. The general condition was alarming. The temperature was 106° F, the pulse 120. There was no mastoid tenderness or swelling. Pressure over the upper half of the internal jugular and cervical triangle was painful. The auditory meatus was filled with fetid pus. The drum membrane was much thickened and perforated posteriorly. The blood count showed increase of white corpuscles (19,000). No plasmodia were found. Ophthalmoscopic examination was negative. The chest and abdomen were normal.

Operation. — The drum was freely incised and the usual incision over the mastoid was made. The bone was sclerosed, and the antrum when opened was found filled with granulations and pus. The sigmoid groove was removed with difficulty on account of the ivory-like character of the bone. The sinus was found thrombosed and covered with foul smelling pus and sloughing tissue. The sigmoid was then opened upwards into the posterior fossa of the skull and downwards toward the bulb of the jugular. The sinus was found to contain a decomposing thrombus to the exposed limit in both directions. At this point it seemed necessary, to prevent further dissemination of septic material, to ligate the internal jugular before taking away the thrombus. An incision along the anterior edge of the sternocleido muscle and careful dissection exposed the vein filled with fluid blood. In this case ligation was made difficult by free venous hemorrhage which obscured the jugular. The vein was, however, ligated about 1 inch above the clavicle and the wound packed with iodoform gauze. The facial and lingual branches were also ligated. The whole of the thrombus was then removed by means of the curette from the bulb upwards an inch into the posterior fossa of the skull. One drachm of foul-smelling pus deeper in was evacuated between the dura mater and the skull. The patient bore the operation poorly and further exploration seemed inadvisable. The cavity was washed out and filled up with iodoform gauze. One hour later the temperature had fallen to 101° F. The pulse was 160.

The patient was fairly comfortable for the next two days. He had a slight cough and complained of pain in the chest. His temperature was about normal and the pulse diminished in rapidity. The wounds were dressed and found free from pus. On the third day after the operation, however, the symptoms became worse. The temperature ranged from 101° to 107° F. with chills. The cough increased, accompanied by expectoration of offensive odor. An examination of the lungs proved negative. He rapidly sank and died nine days after the operation.

Post-mortem examination showed the dura over the tegmen mastoidei for an area 1½ inches in diameter, thickened and granulated. The brain in the same region was intensely congested, but otherwise normal. The sinus over the cerebellum nearly to the torcular Herophili was necrotic. There was a layer of pus between the dura and the skull on both sides of the sinus spreading over the posterior portion of the petrous bone and extending well into the cerebellar fossa. Pus was found surrounding the vein in the neck from the bulb downwards about 2 inches. The lungs were normal, with the exception of a small abscess cavity of doubtful etiology near the apex of the right lung. A pathological diagnosis was made of epidural abscess, left lateral sinus thrombosis and septicemia.

Remarks. — The early constitutional symptoms of these cases are of interest. The first illustrates the so-called malarial type; the second the typhoidal. In the second case valuable time was lost before entrance to the hospital. The patient was supposed to have typhoid fever. When typhoid or malarial symptoms are present in cases of suppurative middle-ear disease, the chances are that the ear disease is primary, and the resulting symptoms, however severe, do not contraindicate an exploratory operation to determine the condition of the sinus; in fact, life may depend on immediate action.

It is interesting to note the rise in temperature without apparent cause four days after ligating the vein. A number of observers have called attention to an elevation for a day or two after the operation, and have considered it due to the elimination of the general sepsis. In my case the rise coming four days after the operation indicated the reverse, namely, an increasing septic absorption.

Every hour of delay in removing the source of infection naturally lessens the chances of recovery. The results in early and late operation are clearly contrasted in these cases. What the result of early ligating in the second case would have been we can only conjecture. Time is important If, as in the first case, operation is done before a general septic invasion the chances of recovery are good. If after, as in the second case, recovery is improbable. Ligature of the vein is theoretically the most complete means of obliterating the channel of infection and is a procedure recommended by some in every case of disintegrating thrombus. So far as 2 cases have any weight, the evidence is in favor of ligating. Yet cases of successful removal of septic clots without ligation of the jugular have been reported by a number of operators, notably by Dr. Macewen, of Glasgow. Although the operation may be difficult and in some cases dangerous, still its omission may lead to greater danger. In my first patient the primary focus was thoroughly removed in both directions until a firm thrombus was reached, but without any subsequent improvement of symptoms.

Conclusions.— In acute cases before ligating the vein remove the purulent material in the sinus until a healthy clot is reached. After this operation, if rigors and elevation of temperature recur immediately, ligate the jugular vein and then remove the entire thrombus above and below until a free flow of blood takes place. If at the original operation no healthy clot is found, ligate immediately. In chronic cases no time should be lost in ligating the vein and completely removing the thrombus.

Clinical Department.

MASSACHUSETTS GENERAL HOSPITAL. CLINICAL MEETING OF THE MEDICAL BOARD.

(Concluded from No. 8, p. 186.)

Regular meeting, December 14, 1900, the president, Dr. C. B. Porter, in the chair.

Dr. Walton showed a

CASE OF BRAIN TUMOR WITH ASTEREOGNOSIS.

This young woman presented herself at the Neurological Department, Friday, November 17th, complaining of numbness in the left arm and leg. The symptom had been of gradual onset, commencing in the leg about six weeks earlier, ushered in by a temporary blur of vision and loss of power. There had been occasional slight occipital headache, and occasional involuntary movement of the left hand, not amounting to spasm. Her movements suggested slight weakness on the left side, or perhaps rather awkwardness; she drooped a little and favored the left leg in walking, but there was no decided limp or toe drop; the separate motions were made perfectly and with good strength, the grasps being practically alike. The knee jerk was exaggerated on the left. Ankle clonus was present, but there was no plantar reflex. In other respects she was well, and was doing her work as a compositor.

On investigating the numbness it was found that when objects were placed in the left hand, she was unable to name them with closed eyes, for example, a knife, a coin, a pencil. On analyzing the anesthesia only a slight degree of loss of tactile sensation appeared, by no means enough to explain her inability to name objects. The temperature and pain senses were also slightly impaired. The so-called muscle sense was lost; she could not tell with the eyes closed whether the fingers were raised, lowered or separated. Examination was otherwise negative, including that of the fundus oculi.

The diagnosis was made of subcortical tumor of the brain in the parietal region. It was decided not to advise operation until the symptoms became more marked. Monday she returned, when Dr. Putnam examined her and agreed in the diagnosis, noting also the fact that there was marked loss of space sense, two points being felt as one on the palmar surface of the hand, until widely separated.

The patient continued her work and was practically well up to Wednesday, when there was rapid onset of left hemiplegia, violent headache and vomiting. Dr. Hamilton attended the patient at her home and Drs. Putnam and Lord were called to see her. Her condition steadily grew worse and she was urged to enter the hospital for operation. She delayed until Friday morning, when her general condition had become alarming. At this time the Babinski reflex was present on the left. The operation was performed that day by Dr. Warren, who will describe the technique.

With regard to the point of election for operation, we benefited by the experience of Drs. Mills and Keene, who operated under very similar conditions, by removing a large flap bounded anteriorly by the fissure of Rolando. The tumor in their case presented so far anteriorly that it was necessary to enlarge the opening forwards by rongeur forceps. In our case it was planned, therefore, that the edge of the flap should extend well forward, so that its centre should be just posterior to the fissure of Rolando; this decision was justified by the result, as the trocar on its first introduction at this point, directed toward the median line, entered the cyst.

Recovery from operation has been uninterrupted; there is now only occasional slight headache, no vomiting, no elevation of temperature. A certain degree of movement is now present in the arm and leg. The Babinski reflex has disappeared.

The importance of recognizing astereognosis (loss of ability to recognize objects, from *στέρεος*, solid, and *γιγνώσκειν*, to know) lies in the cerebral location of the function involved. Of course if tactile sense is entirely lost in a given case, the patient will be unable to recognize objects placed in the hand, and in such a case the symptom is of no material aid in diagnosis, inasmuch as tactile loss may be due to peripheral or spinal, as well as cerebral, lesion; but given preservation, or comparative preservation, of tactile sense, if the patient is still totally incapable of recognizing such objects, the case falls in quite another category.

The recognition of the nature of objects involves a higher psychical process than mere sensation, and requires the co-ordination of various senses, that is, those of posture, space, pressure, temperature and position; the space, position and posture senses enable us to recognize the *form* and *size* of objects, the pressure and temperature sense their *character*, as, for example, whether of metal or of wood; still further, for the proper recognition of objects we require the integrity of our memory for the sensations excited by simi-

lar objects in the past. Such processes are essentially cerebral.

Astereognosis, while generally neglected, has been carefully studied by certain investigators (Hoffman, Dercum, Sailer). It appears from their observations that the symptom may be produced in various ways, and may imply various degrees of diminution of the different factors concerned in sensation.

It would seem that the most constant defects involve (1) so-called muscle sense or posture sense of the fingers; (2) space sense, or the recognition of the number of points coming in contact with the skin, and (3) position sense, or recognition of the place touched. The loss of any one of these sensations may produce the symptom, and it would even appear that astereognosis may occur while all individual varieties of sensation are perfect, including touch, temperature, space and posture. (I have not alluded to pain sense, as this factor can hardly have much bearing on the subject, further than to indicate the disagreeable degree of sharpness, heat or cold, or the violence of contact.) One case of astereognosis has, in fact, been reported in which all the senses were normal. This would imply lesion of a centre high in the psychical scale. In such a centre may be stored the memories of the feel of objects, and to this centre we perhaps appeal for the reproduction of ideas aroused by such complex sensations.

The condition is perhaps somewhat analogous to that of mind blindness and word deafness, though a fundamental difference exists as regards diagnosis, in that stereognosis apparently has a bilateral representation in the brain, for its loss occurs in both right and left hemiplegia. The exact position of these centres, if, indeed, they exist as such, is not established, a fact not surprising, in view of the lack of unanimity regarding the cerebral localization of sensations in general.

In this case, as in that of Mills and Keene, the postcentral region was certainly involved, but neither lesion was sufficiently limited to indicate the exact seat of the stereognostic sense.

DR. WARREN: The points of interest about the operation were in opening the skull. The difficulties in opening on a large scale have long been recognized. Surgeons tried first trephining with a large trephine and nibbling off with rongeur forceps, making a large hole. The disadvantage is that it leaves a large opening. Attempts were made to put the buttons back. That does very well with a small opening, but is not a very desirable thing with a large opening. Then came osteoplastic openings, and they were first done with a saw and afterwards with a chisel. These methods were all rather unsatisfactory because slow, and the chisel, although rapid, produced a tremendous amount of shock. I shall never forget the impression produced upon me by the profound shock occasioned by opening a skull in twelve minutes, so that I feel disinclined to again use that method of opening the skull. The instrument which I have here (the maker's name I am not familiar with) seems to have overcome this difficulty very nicely. All that is necessary is to make your incision through the scalp of the length that you want and not reflect the scalp from the bone, turn up one corner of the flap, and with a trephine opening of small size start in with this nibbling instrument, the small point going in under the edge of the bone, taking slight turns one way and another; thus you cut a swath in the bone of the shape you wish, and then with elevator you pry up the bone; it cracks across the base easily and is turned back with the flap. This incision exposed the fissure of Rolando, and although we found, on turning back the dura, no tumor, as we hoped, Dr. Walton suggested I should make a puncture with a trocar at a certain spot, the ascending parietal convolution, and on doing so a test tube full of clear serum came out from a cyst less than $\frac{1}{2}$ inch from the surface and $\frac{1}{4}$ to $\frac{3}{8}$ of an inch from the surface of the brain. The finger was passed in, went forward; it seemed to be superficial over the ventricle. It was afterwards drained by putting a small piece of Dr. Harrington's tape drain in, leaving it there, sewing up the dura mater and turning back the flap, sewing that up and allowing the tape to come out at this point. Afterwards gutta-percha tissue was inserted as a drain which does not dry up and allows the fluid to escape. Drainage was kept up ten days and then the small hole was allowed to heal.

DR. WALTON, in answer to a question, said: I think the prognosis is extremely doubtful. The cyst may refill and again the cyst may, I suppose, be merely a part of an underlying tumor; this proved to be the case, for example, in the case of Mills and Keene to which I have alluded. In this event the tumor will continue to grow. The future is not very brilliant, excepting that the cyst may of course entirely heal up, and even then we could hardly expect complete recovery of motion, though we might that of sensation.

DR. H. H. A. BEACH presented a case of

OPERATION FOR THE REMOVAL OF A FOREIGN BODY IMPACTED IN THE ESOPHAGUS FOR MORE THAN TWO WEEKS.

CASE I. The patient, a boy eight years old, while playing, was carrying in his mouth a circular piece of tin $\frac{1}{4}$ of an inch in diameter. It slipped into the gullet and became fixed at a point just below the episternal notch, as shown by the x-ray. Soon after, it became impossible for him to swallow solid food. Until his admission to the hospital he lived on liquids. The duration of the impaction suggested the possibility of ulceration from pressure and the inadvisability of attempts at removal by instruments passed through the mouth. External esophagotomy made it possible to reach the coin-shaped obstruction with the tip of the finger and to remove it with forceps. At the same time two fragments of undigested meat presented in the wound and were removed. They may have protected the mucous surface from the sharp edge of the tin during the impaction. The gullet wound was closed by kangaroo tendon, the external wound by provisional sutures enclosing a gauze wick for a few days. He was fed by nutritive enemata for ten days and then beginning with a spoonful of milk his diet was gradually increased to solid food. Discharged well in seventeen days.

BACKWARD DISLOCATION OF THE ULNA; FRACTURE OF THE EXTERNAL CONDYLE OF THE HUMERUS; FRACTURE OF THE RADIUS AND ULNA NEAR THE WRIST JOINT.

CASE II. The whole arm was livid and swollen. The patient, a boy of fourteen years, who had fallen 15 feet from the branch of a tree. Unsuccessful attempts at reduction had been made under ether.

The condition of the arm contraindicated any prolonged manipulation. An x-ray examination showed unmistakable dislocation. Under ether, I found it impossible to adjust the dislocation from some unusual impediment which could only be disclosed by an internal examination of the joint. The arm was prepared and a straight incision of 5 inches was made, as though excision of the joint was to be done. The tendon of the triceps was split and the joint opened. The external condyle of the humerus was fractured and impacted so as to prevent the reduction of the dislocation. I was obliged to dissect off the outer half of the triceps tendon from the olecranon to the point where the posterior ligament joins the orbicular, then pushing the external condyle forward and with a blunt hook pulling backward on the inner side of the shaft of the humerus, the articular surface quickly snapped into the sigmoid notch and the movements of the joint became perfect. The wound was carefully cleaned and tightly closed. The radial and ulnar fractures were set and an elbow splint applied. The fractures have united, the wound has healed and an x-ray picture shows the dislocation reduced. Motions: Rotation good, but slightly limited at the wrist. At this time has about one-half power of extension and very good flexion; is gaining.

RETENTION OF URINE FROM OBSTRUCTION BY THE THIRD LOBE OF THE PROSTATE GLAND.

CASE III. The patient, a man of sixty years, entered with a history of more or less difficulty in urinating for nearly five years. Lately he had grown much worse in frequency and pain, and upon entrance the retention was complete. He was easily relieved by catheters, but only for a few hours. As his temperature was showing some sensitiveness to the instrumentation, it was thought best to relieve his bladder by constant drainage; this was carried out for eighteen days. Upon the removal of the catheter retention again occurred and his temperature again began to rise. His prostate gland felt through the rectum was unusually small. Upon the withdrawal of a sounder (for stone) there appeared to be a ring of tough fibrous material at the neck of the bladder, that suggested a teething ring in shape and consistence. Believing that a division of this structure would relieve his obstruction, I injected a solution of eucaine B. and passed the Bottini instrument, dividing the anterior neck 1 centimetre, the lateral 2 centimetres, and as I could not make an obstruction posteriorly upon withdrawing the instrument, did not divide him posteriorly. He had little or no pain, passed an ounce of blood, but his retention continued. I then made a suprapubic section and finding a valvular projection of the size of the end of the thumb which would allow entrance to, but obstruct exit from, the bladder, crushed it by two lateral constrictions and removed it with scissors. The bladder was drained and his recovery has been uneventful. He now has from 3 to 4 drachms of residual urine, and passes it once in about three hours, without catheter.

DR. R. H. FITZ reported

A SERIES OF CASES ILLUSTRATIVE OF THE CLINICAL IMPORTANCE OF BACTERIOLOGICAL EXAMINATIONS,

in which the diagnosis and prognosis were influenced largely by the bacteriological examinations made by his assistant, Mr. C. H. Dunn, who demonstrated the results of his investigation.

Three of the cases were of inflammation of the respiratory apparatus, and the examination of the sputum showed in one a pneumococcus pneumonia, in the other a pneumonia from Friedländer's bacillus, while in the third the influenza bacillus was the organism concerned.

CASE I. The patient, a boy of seven years, was sent to the hospital as a case of empyema following a kick in the back two weeks earlier. The physical signs were those of solidification of the right lung and the vocal and respiratory sounds were feebly transmitted from the lower lobe. On the day of entrance the temperature was 103° F., the pulse 140, and the respiration 70. The chlorides were much diminished; the blood examination gave 50,000 leucocytes and the sputum showed many pneumococci without tendency to form chains and often contained within leucocytes. The diagnosis of a late stage of pneumococus pneumonia was based upon the bacteriological examination. The crisis, with immediate improvement, began on the day after entrance, and the boy promptly recovered.

CASE II. The patient was a woman, fifty years of age. After two days of malaise she was attacked with cough, dyspnea and sharp pain in the lower right chest, for which she sought medical aid on the following day and was immediately sent to the hospital. On her arrival there were dulness, continued into flatness over the lower right lobe, distant respiratory sounds and broncophany with many fine moist râles at the end of inspiration. Temperature 102° F., pulse 120, respiration 45. The chlorides were absent and the blood count gave 14,000 leucocytes. The liquid, bloody sputum showed a prevalence of Friedländer's bacilli with occasional pneumococci. Death took place on the sixth day after entrance, the patient remaining intelligent and comfortable until the end. The prognostic importance of the presence of Friedländer's bacillus in the sputum thus was confirmed.

CASE III. The patient, a woman of twenty-seven years, was confined to the bed for three days before entrance on account of weakness, although there was also general malaise. There had been no coryza. On the fourth day she entered the hospital suffering from painful cough, dyspnea and cyanosis. Temperature 104° F., pulse 110, respiration 30. There was dulness of the lower right back without modification of respiratory and vocal sounds, but a limited friction sound was heard in the right axilla. On the following day the rub disappeared, the respiratory and local sounds became distant and numerous fine, moist râles appeared in the dull area. The chlorides were much diminished; 12,000 leucocytes were found on examination of the blood. The reddish-brown sputum contained numerous influenza-bacilli within and between the leucocytes. The case followed the course of an atypical pneumonia. Although the temperature remained high for several days and the respirations were from 30 to 50 per minute, the case progressed favorably. Three days after her admission to the hospital there was a discharge of offensive sputum which persisted for a number of days and at the end of a week the sputum contained elastic fibres. The physical signs of the pleuropulmonary disturbance gradually disappeared.

CASE IV. A fatal case of acute meningitis is re-

ported in which the etiology first was made clear after death, although a post-mortem examination was not held. The patient was a girl four years of age, whose illness began with vomiting, followed on the next day by frontal headache and pain in the ears and abdomen. Two days later she left her bed and went to school, but returned weak and cyanotic. On the seventh day her mother noticed that there was diminished use of the left arm and leg. On the eighth day she entered the hospital with these extremities completely paralyzed. Temperature 102° F., pulse 120, respiration 40. The examination of the blood showed 19,000 leucocytes. At the end of a fortnight in the hospital the child died. During this time she remained in a condition of stupor, but suffered from occasional atypical convulsions involving the head and extremities and from inconstant strabismus. Feeding through a tube was necessary. The head was not retracted, nor was there any hydrocephalic cry. The pupils were symmetrical and reacted normally to light. The examination of the ears showed somewhat retracted membranes, which were punctured without any relief. Kernig's sign was absent. The examination of the chest was negative and there was no elargement of the spleen. The etiology of this case was made known after examination of the fluid obtained from the spinal canal by lumbar puncture after death. It proved to be one of sporadic meningitis from pneumococcal infection.

IDIOPATHIC DILATATION OF THE COLON; CHRONIC RHEUMATIC ARTHRITIS; CHRONIC MITRAL ENDOCARDITIS; HEMIPLEGIA; EMBEDDED NEEDLE.

DR. FITZ showed a patient who was admitted to the hospital with the diagnosis of an abdominal tumor, but who was interesting also from a complication of diseases. The enlargement of the abdomen, which first attracted attention during the summer of 1890, resembled that of a woman seven months pregnant, and was found to be due to a persistent dilatation of the sigmoid flexure made prominent by contraction of the abdominal muscles.

The patient, an Englishwoman, single, forty-four years old, had acute articular rheumatism twenty years ago and was confined to her bed for six weeks. Nine years later, after an intervening period of good health, she suffered for two years from arthritis involving many of the joints and causing permanent flipper hands, partial dislocation and impaired mobility of the distal phalanges of two fingers of the left hand and a stiff knee and ankle. This illness had been diagnosed in England as rheumatoid arthritis. She was treated in various hospitals in Bath and elsewhere and was bedridden most of the time. The radiograph of the hands showed no deformity of the articular ends of the bones, but a piece of a needle, more than an inch in length, was apparent in the palm of the right hand. The patient had no recollection of the passage of a needle through the skin within the last fifteen years. She had never suffered discomfort from the needle. Nine months ago, having been constantly at work since her emigration to this country in 1892, the right arm and half the face became paralyzed and the speech was disturbed. She speedily recovered from the attack. At present there is a systolic murmur confined to the apex, but there is no enlargement of the heart and there have been no symptoms of cardiac insufficiency.

DR. SHATTUCK: Does that disappear or stay all the time?

DR. FITZ: It persists.

DR. RICHARD C. CABOT: How do the bowels act?

DR. FITZ: She has had more or less tendency to constipation, but not sufficient to cause any particular distress.

DR. F. C. SHATTUCK: Is the colon involved?

DR. FITZ: No; the sigmoid itself is large.

DR. C. A. PORTER reported a case of

OPERATION FOR GUNSHOT WOUND.

I should like to speak of a case on which I operated late this afternoon, to show the brilliancy with which Mr. Walter Dodd can make a diagnosis with the x-rays, for I think it is doubtful if we all recognize how valuable a man he is to us. A man entered the accident room this afternoon who had shot himself with a 32-calibre revolver in the head just above the right parietal eminence. It was evident that the bullet had entered the cranial cavity, as disintegrated brain tissue appeared in the wound. He was profoundly unconscious. There were no localizing signs or symptoms whatever, except perhaps a little swelling and redness just above the left ear.

Two plates were made by him which, as you can see, show the bullet distinctly in the left side of the brain. I will not repeat his calculations, simply because I do not understand them. I asked him *where* the bullet lay, and he said: "Trephine 1 inch in front of the ear and an inch above the zygoma on the *left side*." I did this without ether, using a ¾ inch trephine. The dura was tense and blue; the circle was enlarged to 1¼ inches in diameter with rongeur forceps, and the dura was opened. Blood clots under tension escaped; the breathing became quieter. Exactly in the centre of the opening was the clearly cut wound of exit from the brain, the bullet having passed quite through both hemispheres; as the clots came for the most part from in front, the opening was enlarged in that direction. The bullet had ricocheted from the skull without injuring the dura and glanced forwards and inwards. It was finally recovered in the centre of the anterior part of the temporal lobe, the little finger having been introduced along the track made by it. Gauze wicks were placed in the operation wound and that of entrance, and the man put to bed. He died, unfortunately, early in the morning.

DR. C. B. PORTER: I want to show this case as a case of fracture of the kidney, with bloody urine. He comes from the Norfolk Club, and was kicked in the belly by a horse, one hoof striking here (indicating), and one here (indicating). He came in the next morning and there was dulness through this line here (tracings upon body). Immediately after the injury there were pain, vomiting and bloody urine. At the time of entrance he was passing considerable quantities of blood. He was in a condition of shock. Examination showed dulness on the right side from the fourth rib downwards in the axillary line, tender, swollen, rigid abdomen. There was no change in this line by changing his position in the bed, but the interesting thing is that from the time of entrance his temperature commenced to drop, which led me to hold my hand. He went on uninterruptedly a number of days, his pain clearing up and this dulness

slowly and gradually disappearing. He got up one morning in a hurry and went to the bathroom and commenced to have another rise of temperature. I was afraid that he had lighted up the condition for which he came in and that we should have more bloody urine, but he did not have bloody urine follow that. He is now all right, has been discharged, and came in merely to be shown. It is interesting to see that in cases of fracture of the kidney it is possible at times for them to get well without operation. Another interesting thing in connection with this case is that from the same club last year I had another case of the same kind, which also got well without operation.

Medical Progress.

REPORT ON DERMATOLOGY.

BY JOHN T. BOWEN, M.D., BOSTON.

(Concluded from No. 8, p. 188.)

PROPHYLAXIS AND CONTROL OF LEPROSY IN THE UNITED STATES.

In a paper read before the American Dermatological Association in May, 1900, Morrow [3] asserts that the question of leprosy has been chiefly agitated by alarmists in the daily press, although the association was the first of the scientific bodies to call attention to its prevalence in the United States. By this and other means an act for the investigation of leprosy was passed by the United States Congress in April, 1898, which provided for the appointment of a commission of medical officers of the Marine-Hospital Service to investigate, and to report what legislation is necessary to check the spread of the disease. Nothing has been heard from this commission.

Dr. Morrow points out that our leper population has been largely increased by our territorial acquisitions. In Hawaii the native population is largely tainted with leprosy, as is the case with Cuba and Puerto Rico. The Philippines are one of the chief Eastern centres of leprosy which are continually exposed to fresh contamination by their nearness to China and Japan. The danger to us will come from the exposure of sailors and soldiers, of administrative officers, and those engaged in trade in the islands. The leprosy that has been found in Southern and Central Europe within the last century has come almost entirely from soldiers, sailors or administrative officers who have lived in the colonies where leprosy occurs. Of the 100 cases seen in Great Britain during the last ten years, all, with possibly 2 exceptions, contracted the disease in the leper colonies of England. Of 1,500 cases of leprosy in Spain the great majority were soldiers or monks who had contracted the disease in the Philippines, the Canaries, or Cuba. Additional opportunity for the spread of the disease is afforded by the open-door policy in China, and by the increased quickness of transportation. The Chinese have been the most active disseminators of the disease in modern times, and its spread in many countries can be traced to coolie immigrants.

The most obvious method of prophylaxis is to exclude all leprous immigrants, as far as possible, realizing that an absolutely perfect quarantine is impossible. It could be made more effective by international co-operation with countries where leprosy prevails, and by examining emigrants at points from which they embark. All immigrants from leprous families or from leprous districts should be registered and kept under observation for several years. This system is in operation in Hawaii with the result that of 2,600 Japanese laborers brought to Hawaii there have been only 6 cases of leprosy. Skilled experts as quarantine inspectors would also be an advantage.

With regard to leprosy as it exists within the United States, Morrow says that the leper is still an outcast in some parts of the country. No organized effort for the control of the disease has been made. Louisiana has provided a special asylum for lepers, but Dr. Dyer declares that its operation has been ineffective. The enforcement of the law of isolation has been more vigorous in California than in most other States, especially in the case of Chinese immigrants. In New York the health authorities have undoubtedly been hampered by the conflicting opinions of the medical profession with regard to contagiousness. Too much importance, in Morrow's opinion, has been laid on negative facts of contagion; as, for example, that lepers have lived for years in New York City without communicating the disease. The same could be said of tuberculosis or syphilis. In Louisiana there is much evidence of contagion, as shown by the great increase in the disease and in the large numbers of indigenous cases.

Morrow states his impression to be that leprosy is slowly increasing in the United States. Assuming therefore the necessity for the control of this disease, the question arises, whether it should be divided among local and State authorities, or be assumed by the national government. The results of the policy pursued by municipal and State boards of health have not been satisfactory. There has either been nothing done, or the patients have been cruelly imprisoned in a pest house. Co-operation between the different States would be necessary, and the expense is considerable, so that, the disease being very irregularly distributed, it would be hard to persuade the authorities of a State where there was very little, if any, leprosy to provide an expensive building for isolation. Morrow thinks that the control of leprosy should be given to the national government. Isolation or segregation is undoubtedly the most effective means for controlling this disease. It is necessary that all cases should be reported. Morrow thinks that a board of competent experts should be appointed to determine the existence of the disease or not, and he is not prepared to say that every leper should be seized and confined until he dies. A certain amount of discrimination in the selection of suitable cases for segregation should be practised. There would seem to be no reason for regarding an anesthetic leper without cutaneous or mucous membrane changes as dangerous to the community. Hygienic homes or asylums should be provided by the government, and should be made as comfortable and attractive as possible, giving the patients an opportunity for work or recreation. Segregation has never been thoroughly carried out in countries where it has been tried, on account chiefly of the opprobrium attaching to the disease and the desire for concealment. The removal of the popular prejudice against, and fear of, the disease, would render seg-

[3] Lepra, December, 1900.

regation much easier of accomplishment. "Instead of the traditional lazaretto with its veiled inscription, 'All hope abandon, ye who enter here,' asylums should be provided which would be suggestive in their surroundings and mode of management of a sanatorium rather than a prison. These institutions should hold out assurances of humane care, of medical treatment, and, if possible, a hope of cure."

"SARCOID" TUMORS OF THE SKIN.

Kaposi has proposed the name "sarcoid" as a provisional one for certain tumors of the skin that bear a striking resemblance to sarcomata in some respects while in others they differ from them widely. Kaposi includes under this heading: (1) Mycosis fungoides; (2) lymphodermia cutis; (3) sarcomatosis cutis; (4) sarcoma cutis proprie dictum. Fendt[5] would separate mycosis fungoides from this group, as a distinct, well-defined infectious disease, as well as lymphodermia cutis, which includes leukemia and pseudoleukemia cutis. He throws out also sarcoma cutis proprie dictum, as Kaposi includes in that the isolated sarcomata, and typical melanotic sarcoma. From sarcomatosis cutis he separates the multiple, idiopathic pigmented form, so that he has left finally only the form of generalized sarcoma, described as occurring on the trunk and extremities in the form of a hundred or more finger-nail sized and larger, bluish-red flattened or projecting nodules which are situated in the corium and subcutaneous fat tissue and are of firm, elastic consistency. There are no enlarged glands, no abnormalities to be found in the blood, or constitutional disorders. It is to this class then that Fendt wishes to restrict the term "sarcoid" tumors, a far different conception from that of Kaposi. This class of cases is the one that responds to the administration of arsenic, and about 25 such cases are said to have been reported. In most of them, however, an absolute cure could not be claimed. In several cases of this variety an intercurrent erysipelas caused the tumors to disappear.

Fendt reports a case observed in Herxheimer's clinic in Frankfort, that of a boy of sixteen, who had first observed six months previously a small, painless nodule on the right arm, which was soon followed by numerous nodules on various parts of the body. When seen nothing abnormal could be detected in the internal organs. Scattered over the body were fifteen to eighteen tumors, which were rounded and hard and had their seat chiefly in the subcutaneous tissue. A few of the tumors were of a violet color, most of them not colored. The patient was immediately treated with intravenous injections of arsenious acid, beginning with .01 daily, and increasing to .02. Examination showed the blood normal. There was a constant appearance of new nodules for a time. Later they ceased to appear and the old ones became smaller until at the end of five months they had all disappeared, without leaving a scar. Asiatic pills were substituted for the intravenous injections on account of local pain and swelling from the injections.

Histologically the cutis was found to be filled with a collection of large round cells, which were in part present as encapsulated tumors from which the connective tissue had in great measure disappeared, in part represented a true infiltration, with the connective tissue present, but greatly affected. In certain places the new-formed cells had undergone a certain amount of degeneration. Although the histological picture was that of sarcoma, it was not considered proper to class this definitely among the sarcomata, inasmuch as one of the laws of sarcomata that they grow progressively and do not disappear spontaneously was not followed in this case.

Another case from the Frankfort clinic is described in which a woman of sixty presented a diffuse infiltration of the skin of the eyelids and other parts of the face, and of the breasts. Over other parts of the body were scattered tumors of apparently different ages and different sizes, slightly pigmented and in some instances umbilicated. There was no enlargement of the lymph glands. The affection proved to be a lenticular cancer, and the case terminated fatally. It is thought that a case reported by Joseph under the head of sarcoid tumors was probably a cancer and analogous to this, and it is pointed out that the clinical diagnosis between carcinoma and sarcoid tumor may be very difficult.

The conclusions are reached: (1) That the form of sarcomatosis here described as sarcoid tumors of the skin ought not to be classed with the sarcomata, as they vary from sarcomata both histologically and clinically. Their etiology is at present obscure, but it is probable that they represent an infectious disease. (2) Carcinomatosis cutis can as a rule be excluded only by a microscopical examination.

TREATMENT OF CUTANEOUS AFFECTIONS WITH FINSEN'S CONCENTRATED LIGHT AND WITH THE X-RAYS.

Bie,[6] Finsen's assistant in his institute at Copenhagen, remarks that Finsen, in his first communication on the subject of concentrated light, indicated the superficial local bacterial affections as especially suited for treatment by this method. Lupus vulgaris was first chosen as a test, as it fulfilled these indications and also offered a good test on account of its obstinacy. The treatment is based on the capacity of the blue, violet and ultra-violet rays to destroy bacteria, provoke an inflammation of the skin and to penetrate through an anemic skin. It is not impossible that the inflammation alone may be the cause of the cure, and in any case it is remarkable that the two affections, apart from lupus, that have given the best results, epithelioma and alopecia areata, are not of known microbic origin. It is asserted that alopecia areata can be healed comparatively quickly by means of the light treatment, and the favorable result may be due to the active inflammation set up in the skin, as other inflammatory agents may also cause the hair to grow. The light has the advantage over applications of penetrating deeply into the skin.

Finsen has exhibited a number of patients in the Copenhagen Dermatological Society, to show that cutaneous epithelioma also may be healed by the light treatment. In this case also we do not know whether the beneficial effect is due to the destruction of possible bacteria, to the inflammation of the skin, or to both factors. In some of the cases of epithelioma so treated there was a sloughing of the tissues shortly after the beginning of the treatment. This is the more interesting since it has never been observed in more than 500 cases of lupus and other cutaneous affections treated in this way. Nor has

[5] Fendt: Archiv. f. Derm. und Syph., Bd. liii, H. 2 and 3.

[6] Dermatologische Zeitschrift, August, 1900.

necrosis been seen when normal skin has been treated experimentally; normal skin treated with strong concentrated light exhibiting redness, swelling, infiltration and usually the formation of bullæ, but never necrosis. Microscopical investigations have shown that when normal skin is exposed to a weak electric light there is a serofibrinous or cellular exudation, a swelling of the collagenous tissue and epithelium, and a liquefaction of these tissues; when a more intense light was employed there was a thrombosis of the cutaneous vessels, but the possibility that this was due to heat could not be fully excluded.

Of 16 cases of epithelioma treated in this way by Finsen, the treatment was without result in 3. Five patients were improved but not healed, 1 patient was apparently cured, but had a recurrence shortly afterward. Seven patients were cured. Of the 5 who were improved but not cured, in 2 the affection was seated on the eyelids, where it was feared to use a strong light. The 7 cases that were cured had remained without recurrence from six months to two and one-half years. Whether all these cases have been permanently healed it is of course impossible to say as yet. In all the cases that were cured the lesions were small and superficial and therefore well suited to the treatment. In the case of those previously treated, more was accomplished by this method than by previous measures. Finsen declared, in conclusion, that the method could be undertaken with hope of success only in the cases of epithelioma that were superficial and sharply bounded, and were situated in places suitable for the treatment.

Loewald[7] in the same number discusses the value therapeutically of both the concentrated light and x-rays. Until quite recently the inflammatory properties of light were falsely interpreted. So-called eczema solare was thought to be due to the heat rays, but doubt was cast upon this by the observation of similar phenomena after walking on snowfields, on high mountains and after exposure for a long time to a strong electric light. It was then found that the cutaneous inflammation was due, not to the heat rays, but to the chemical rays, especially the ultra-violet, and less prominently to the violet and blue rays. The green, yellow and red rays are not in the least concerned.

It has been proved that bacteria may be killed by light, and the best observers have found the ultra-violet, violet and blue rays again the most effective. Finsen succeeded, by means of concentration, in killing various kinds of bacteria in a few seconds. The results of the treatment of lupus by this method are said by Finsen and his pupils, and by Lassar, to be especially favorable. An hour's treatment daily causes an inflammatory redness and swelling, and then a shrinking up of the lupous tissue and the formation of a cicatrix. The treatment is painless, and no ill results have been observed. The long duration is a great objection, as light cases of small extent require from four to six months, the severer forms one to two years. The results in lupus erythematosus were variable. Of the 30 cases reported, in some there was permanent healing with good cicatricial tissue, while others were obstinate and showed a continual tendency to recurrences.

Turning to the x-rays, the unfavorable effects on the normal skin are not seen immediately after the exposures, but appear usually several weeks after the last sitting. They take the form of redness, with or without succeeding inflammation, decolorization of the skin, or increased pigmentation, transference of pigment toward the periphery, simple scaling of the epidermis, the formation of bullæ with serous or pustular exudation, edema of the corium and the formation of sloughs and ulcers. There is much pain and increased sensitiveness of the skin. The course is remarkably long. The hair often falls out and the nails may become brittle and fissured, or may be wholly lost. Histologically a thickening of the epidermis, increase of keratohyalin, atrophy and disappearance of hairs, follicles and glands have been noted. Gassmann observed peculiar changes in the walls of the vessels and a degeneration of the subcutaneous tissue. These unfavorable effects on the skin are estimated by Unna as occurring in about 1% of the cases.

In employing the rays therapeutically these unfavorable effects must be taken into account. Practically the danger from them can be reduced to a minimum in practised hands. In lupus vulgaris the first effect of the rays is a yellowish discoloration of the skin, which is soon followed by a dermatitis, characterized by redness and slight burning. If the rays are interrupted at the moment when the yellowish color appears, there is little succeeding dermatitis. When the dermatitis has disappeared, the rays are renewed, and healing follows with cleaning of the ulcers, cicatrization and separation of crusts. A number of observers have reported favorable results from this method, yet it does not protect from recurrences. It is, like Finsen's light treatment, of very long duration, but has the advantage over the latter that it may be used in very extensive cases. The cosmetic results are in every way equal to those of Finsen. Several writers report good results in chronic eczema with this treatment. The early results in many of these cases appear to have been better than the later, as there were recurrences and the rays seemed to lose their effect. No especially good results have been noted in psoriasis. Diseases in which a temporary baldness is desirable, as favus, sycosis, tinea tricophytina, have been favorably influenced.

With regard to hypertrichosis, Schiff, Freund and Jutassy have reported favorable results. It is, however, a very nice matter to adjust the application so carefully that no dermatitis is caused, and several cases of disfiguring scars have been reported. A brownish discoloration of the skin is noticed one or two days before the hair falls. The hair of brunettes becomes white just before it falls. Twenty to thirty sittings are necessary as a rule, but a single series of treatments is not sufficient, as a new growth begins two or three months later. It is said to be permanently removed if three or four sittings are practised at intervals of six weeks. The rays have also been tried in pigmented and angiomatous nevi, elephantiasis, etc.

Is has hitherto been impossible to explain the action of the Röntgen rays on the skin. Shutting out the heat rays and the light has not been able to prevent the dermatitis, or shutting out the electrical action also. It cannot, as experiment has proved, be ascribed to the action of the chemical rays. Experiments made to test the bactericidal properties of the rays in the case of lupus have not shown them to have this power.

What is the outlook for the treatment of cutaneous

[7] Dermatologische Zeitschrift, August, 1900.

affections by the x-rays? It is to be feared that the great hopes cherished by some will not be realized. In the majority of affections in which they have been tried, we possess numerous methods which give just as good results without the danger of injurious after effects. It is possible that much may be done by combining phototherapeutics with other methods. It cannot be doubted that the chemical rays of light, as well as the Röntgen rays, have a peculiar action on certain diseased conditions of the skin, and there can be no doubt that there is a certain resemblance in the method of action of the two kinds of rays. It is possible that this may prove a means of solving the secret of the Röntgen rays.

Reports of Societies.

NEW YORK NEUROLOGICAL SOCIETY.

STATED meeting, January 1, 1901, FREDERICK PETERSON, M.D., president.

SPINAL ACCESSORY PARALYSIS.

DR. PEARCE BAILEY presented a man who last March had been operated upon for suppurating glands of the neck. During the operation the spinal accessory nerve had been cut. There had been immediate and complete paralysis of the sternomastoid and trapezius. About six weeks later the nerve had been sutured, with considerable improvement in the symptoms. During the past summer a weakness had appeared in the deltoid and in the muscles supplied by the musculospiral nerve. There had been considerable return of power. A fairly large incision had been made at the operation in the region of the mastoid. On inspection the shoulder on the affected side was seen to droop and the scapula hung away from the spine. The only anesthesia observed had been limited to the ear and over the right side of the face — an area corresponding to the supply of the great auricular nerve, which had undoubtedly been cut at the same time. There was now marked hyperesthesia over the distribution of this nerve. When first seen the position of the head had been slightly towards the injured side and a little downward.

DR. E. D. FISHER suggested that there was a psychical element in the case. He said that on pressing along the muscles of the arm slowly there was no reaction, but if done suddenly there was a spasmodic contraction of the muscles of this region.

DR. JOSEPH COLLINS did not think the whole condition had been explained by Dr. Bailey, for, in his opinion, there were symptoms of root involvement over a rather extended area. He could not understand how these could be explained by mere section of the spinal accessory nerve. The tic of the facial muscles and on either side of the neck, and the narrowing of the palpebral fissure, appeared to be associated with fibrillary twitchings. This would indicate a rather extensive involvement of the anterior roots in the cervical region. He would also like to know about the condition of the pupils.

DR. F. PETERSON said that he had seen this case before, and had been interested in the complications. He had seen the man before the appearance of the twitchings, and on first noting the latter he had been inclined to assume that it was hysterical. However, after having made the electrical examination he had felt sure that it was not hysterical, but a pressure palsy involving a number of nerves, possibly as a result of sleeping with the arm in an upward position.

DR. BAILEY said that the suppurating gland had been situated deeply underneath the sternomastoid. When first seen by him last April there had been a typical picture of paralysis of the sternomastoid and trapezius, but no symptoms referable to the arm, no tics and no functional disorders. The man had been completely incapacitated for work, and this probably explained his psychical condition. The irritative condition of the face was probably explicable by the formation of new connective tissue in the scar. As soon as his attention had been called to the pressure palsy he had been watched at night and prevented from sleeping on his arm, and this had resulted in immediate and decided improvement. It was probable that in time the man would get fairly good use of his arm.

FACIAL HEMIATROPHY.

DR. MAX MAILHOUSE presented a man, twenty years of age, without neurotic family history. Twenty-two months ago a discoloration had appeared on the right side of the face below the lower lid. It had begun as a pale depressed spot. When first seen by the speaker, the right side of the face had been much atropied, and the beard had been absent on this side. The mouth had been drawn to the right and the right half of the tongue very much atrophied. The apparent prominence of the right eyeball was due to retraction of the lower lid. The hair of the right half of the scalp was grayer than on the left, and was falling out. He had been losing his teeth on the right side. The nasal cartilage was wasted, and its tip was turned to the right. The muscles of mastication were also atrophied, and this was associated with spasmodic pain. There was a fibrillary tremor of the large muscles. The affected muscles reacted feebly to faradization, and normally to galvanism. No scleroderma was found. For the past two months there had been twitching of the muscles on the right angle of the mouth, and at times after laughing this angle would remain retracted. At such times there was a very tender spot situated in front of the ear. A blow of moderate severity had been received over the mouth ten years ago. No other etiological element could be elicited, and even this one seemed to have but little weight. The atrophy of the tongue seemed to be a strong argument for the theory that this affection is a trophoneurosis.

DR. C. L. DANA said that he had met with several such cases, and had found them all quite obscure. At one time the view had prevailed that it was a trophoneurosis due to some lesion of the trophic root — a condition very difficult to understand. In one of his cases there had been a typical diffuse trigeminal neuritis occurring in a woman of about forty years. The attack had begun with herpes and neuralgia, and had been followed by a general neuralgia in the course of the fifth nerve. After this there had been atrophy and some anesthesia, and finally a peculiar pitting of the face, like that from smallpox. In another case the trouble had begun, as it often did, with pigmented spots and neuralgia, and this had been followed by anesthesia in spots and a typical

progressive anesthesia involving all the tissues, including the masseter muscle and the bone. In this woman there had been deafness and some disturbance of vision on the affected side. It was difficult to understand how a trophic or central lesion would cause all these symptoms. A herpes was almost always a sign of peripheral trouble.

Another case had been in a woman, who had married at the age of seventeen. Her husband had died, it was said, of syphilis a few years later, though the woman denied ever having become infected. She had had a progressive facial hemiatrophy for a number of years, and had finally developed atrophy on the same side, affecting the arm and the leg. In none of his cases had there been anything indicating the true nature of the etiology. Perhaps the best explanation was that of a peripheral lesion as a starting point. He had obtained no definite results from treatment, perhaps because he had not been able to keep these cases under treatment for a sufficient length of time. If the trouble were peripheral, Dercum's idea of resecting the trigeminus seemed to be worthy of careful consideration.

DR. FRAENKEL asked if any difference had been observed in the behavior of the sweat glands on both sides of the face.

DR. MAILHOUSE replied that there had been less sweating on the affected side.

DR. JOSEPH COLLINS thought the disease could be explained just as well by a central as by a local lesion. He was inclined to think that the patient just presented had a lesion in the pons, in the area of central representation of the sympathetic nervous system in the pons. The lesion was probably a slowly progressive one, such as gliomatosis. There already seemed to be involvement of the motor nuclei of the medulla oblongata. The enlargement of the pupil would be explained by an irritation of the sympathetic which had gone on to paralytic effects.

PROGRESSIVE LINGUAL HEMIATROPHY.

DR. C. L. DANA presented in connection with the last case a rather rare form of progressive lingual hemiatrophy. It occurred in a man, twenty-six years of age, who had had the trouble three years, but had been otherwise in perfect health. The half of the tongue was gradually wasting away, and this was associated with fibrillary twitchings. The patient was a healthy young medical student without history of syphilitic infection or nervous heredity. It did not seem to him necessary to suppose that there was a gliosis, for Mendel had already shown that there is a change in the motor root of the trigeminus. Of course, these changes might be secondary to degeneration and partial destruction of the nerve.

DR. PETERSON said he was inclined to believe with Dr. Collins that some central lesion would best explain the condition. He had seen several cases, but all of them in a much earlier stage. In none of them had the tongue or the muscles of mastication been involved, or had they presented the same pupillary phenomena.

DR. MAILHOUSE thought the dilatation of the pupil might be explained by a similar process involving the sphincter pupillæ and causing weakness. Hoffmann had reported some improvement from the use of galvanism for half an hour daily.

NEW YORK OBSTETRICAL SOCIETY.

STATED meeting, Tuesday, January 8, 1901, the president, DR. H. J. BOLDT, in the chair.

DR. JANVRIN presented a

SPECIMEN OF LARGE MYOMATOUS GROWTH OF THE UTERUS.

The history was as follows: Patient single, forty years of age, menstrual history regular, no pain or bleeding. One month ago she had her normal period, which continued for several days, after which she began to flow freely. The hemorrhage was controlled somewhat, but she continued to flow for several weeks. Upon examination, at the end of three weeks, a large abdominal growth was found and the tumor removed which is here presented. Several cysts of the ovaries were removed at the same time. The case was of interest because no hemorrhage had occurred until the last month, although the mass was of large size. The reason for this lies in the fact that the tumor is probably of the cystic variety.

DR. H. J. BOLDT presented a

SPECIMEN OF TUBAL PREGNANCY,

in which the fetus of two months was found still within the tube. The great interest in this case lies in the fact that operation was performed as the process of tubal abortion was taking place. The abdominal extremity of the tube is dilated to a diameter of 1 centimetre. The uterine end is completely occluded. The tube is $2\frac{1}{2}$ centimetres in diameter at the thickest point. The patient had been bleeding for three months at irregular intervals, accompanied by cramp-like pains. During the week before operation the bleeding was very profuse, so that her physician (who thought that the patient had an intra-uterine pregnancy) said that she would abort. Large clots were expelled per vaginam. The patient was very anemic, and suffered great pain. In the abdomen there was a large quantity of blood which had escaped at different times, shown by the varying degrees of consistency; some clots were recent, bleeding continuing from the tube; while some were very firm and yellowish-red, the latter being on the floor of the pelvis. The bleeding for such length of time without completion of the abortion is the main interesting feature.

DR. VINEBERG said that the case was of great interest, showing as it did that we may get as profuse a hemorrhage from the uterus in ectopic gestation as from an intra-uterine abortion. He also emphasized the advisability of giving an anesthetic in cases of supposed abortion in order to make a careful diagnosis of the exact conditions.

DR. ABRAM BROTHERS mentioned the fact that some men thought it unnecessary in cases of tubal abortion to perform laparotomy, or to exsect the tube. But in cases like this one of Dr. Boldt's, where the diagnosis of tubal abortion is made, and where the patient may lose her life from exsanguination, the loss of blood occurring externally or in the peritoneum, one is justified in doing an abdominal section and removing the diseased tube.

DR. JANVRIN remarked that in many cases upon which surgeons are called to operate there is really a tubal abortion present, and no rupture of the tube itself. It is rare for hemorrhages to continue from a tube for two or three weeks without abortion being

complete. In most cases tubal abortion takes place inside of a week. In his opinion there was no question of the necessity for operation in any case where hemorrhage was going on.

DR. BOLDT said he believed that an impregnated tube should be treated as one of malignant disease and operation was therefore indicated.

Dr. Boldt read a paper entitled

I. THE DEFINITION OF SEPTICEMIA AND PYEMIA; II. THE INDICATION FOR VAGINAL HYSTERECTOMY AND FOR ABDOMINAL SECTION AND DRAINAGE IN PUERPERAL FEVER.

The writer, in reviewing the bacteriology of the ailments under discussion, said that while there were many varieties of streptococci, they could be divided into three classes or varieties, depending upon their virulence. In order to show the various definitions for septicema and pyemia and their mingling with the terms "septic infection" and "septic intoxication," thus creating confusion, the author quoted from a number of recent textbooks and dictionaries. So different in meaning are these various definitions that one is necessarily confused in choosing the correct term for a given pathological condition.

The best definition for septicemia is given by Coplin in his "Manual of Pathology," third edition, published in 1900. This is found on page 389 under the term "mycoses of the blood." He states that "in these the bacteria are present and multiplying in the circulating blood in which their products are generated. The intensity of the septic phenomena is augmented by the greater production of the poison, and not having even the barrier of protection afforded by the necessity of osmosis or absorption, they are enabled to engender lesions not presumed to occur, at least not to the same extent, in either sapremia or local infection. The embolic production of abscess is the essential element of pyemia, a disease recognized by surgeons as septicemia plus the infected emboli to which are attributed metastatic abscesses."

Delafield and Prudden, in their "Pathological Anatomy and Histology," fifth edition, state that "if from a focus of suppurative inflammation due to microscopic organisms, or if from a point of entrance of microscopic organisms without local reaction, the germs and their product become distributed through the body, inducing disease, the general condition is called septicemia. If in the invasion of the body by the microscopic organisms and their products new supplementary foci be established, it is now customary to designate the condition pyemia."

Dr. Boldt in his paper makes use of and favors the terms "acute" and "chronic" bacteriemia. He defines "acute bacteriemia" as a blood disease caused by microscopic organisms invading the circulation from some primary seat of infection. These infection-producing elements multiply so rapidly in the blood that the patient usually succumbs within five days after the disease begins. Usually the parasitic germs are streptococci pyogenes, but other pathological germs may be present also. Chronic bacteriemia (or pyemia) is likewise caused by the invasion of the system by microscopic organisms, but they disseminate from an infected thrombus. They are not diffused into the system in one large quantity, neither are they possessed with the same foudroyant virulence from a clinical standpoint. The production of the abscesses found in the condition called pyemia, and upon which the pathological difference between the two conditions depend, is due to the parasitic organisms finding a resting place outside of the blood circulation, and there giving rise to abscess formation. That there is a decided difference in the virulence of streptococci no one will deny; for instance, an incised wound of the finger may be infected with pus containing streptococci, and yet slight local disturbance result. On the other hand, during an operation on a patient with puerperal septic infection a small puncture of the epidermis may result in grave local and constitutional symptoms. When septicemia originates from infected thrombi, the infection elements, in the writer's opinion, are diffused to a great extent through the lymph channels. In acute bacteriemia there is usually but one chill, or in some instances there is none. The infection is intense and occurs suddenly. There is usually no repetition of the chill, because the rapidly multiplying organisms are already in large quantities in the circulation.

In chronic bacteriemia, on the other hand, there are repeated chills, due to fresh additions of septic organisms into the system. The pathological differences found on autopsy are well known, and harmonize with the manner in which the pathological germs are introduced into the system. It is impossible to distinguish septicemia from pyemia by a bacteriological examination of the blood or tissues. The author proposes for simplicity to limit the term "septic infection" to "local sepsis," reserving the term "acute bacteriemia" for what is ordinarily called septicemia, and the term "chronic bacteriemia" for "pyemia," so called.

Both acute and chronic bacteriemia are caused by microscopic organisms, but one is of short duration, the other long. So much then for the definitions of the terms to be used in the second part of the paper.

If the definitions and the pathological changes of acute bacteriemia are kept in mind, it should be evident that surgical intervention, like extirpation of the uterus, whether performed by abdominal or vaginal route or an abdominal section with drainage, must be futile. The author believes that it is a common error to report cases of local sepsis with severe constitutional symptoms as cases of acute bacteriemia, and thus much confusion is caused. In this way, it has been claimed that hysterectomy for acute bacteriemia has been followed by recovery. In the opinion of the writer, no such result ever has been or ever will be achieved by the surgical intervention alluded to for the cure of acute bacteriemia. If ever we should be fortunate enough to find a remedy for acute bacteriemia it will be found in the realm of serum therapy. The writer then said that this decisive assertion had been verified by clinical experience, extending over the past eighteen years. During this time he had performed all of the major operations on a large number of patients, yet he had not seen a single instance of recovery from acute puerperal bacteriemia (general puerperal sepsis), even if operations had been performed. In his opinion, the only effect from the operation on such patients was to hasten death. He had continued to perform the various operations for acute bacteriemia, thinking that it might be possible to save a life, because others had maintained that they had been successful, but it is evident to him that those who made these assertions were mistaken in the view as to what acute bacteriemia

(septicemia) is. There is no doubt, however, that the operations alluded to in the title of the paper are indicated in some patients ill with septic infection.

It is then of the greatest importance to know when to operate, and for what conditions. It is not easy to make exact diagnoses, but as a rule we can come to a correct conclusion after observing the course of symptoms for several days. Some patients ill with sapremia will show such severe symptoms that they simulate acute bacteriemia, but a short observation will usually decide the question. Occasionally patients who suffer from toxemia (sapremia) may show positive indications for the removal of the organ giving rise to the infection. To illustrate, B. S. Schultze [1] mentions the following case: The patient was delivered of a dead child on September 7th, the placenta did not follow, and upon traction the cord tore off. The physician could not reach the placenta to remove it. In the hospital it was found impossible to remove it, even under full anesthetics. She began to show symptoms of infection two days after delivery, and her condition became much worse. She had frequent chills and high temperature, so that it was evident that she would die if the cause of the infection could not be removed, especially as peritoneal irritation had begun. On September 13th a supravaginal amputation was made. The uterine bicornis was gangrenous nearly to the peritoneal cavity. The patient recovered. Another case was reported by Sippel,[2] in which the placenta was removed by manual extraction, but some placental fragments remained which Sippel could not remove because of the softened condition of the uterus. The patient was extremely anemic from blood loss, which was large. Septic endometritis resulted, and thirteen days subsequent to delivery supravaginal amputation was performed, recovery resulting. An infection by microscopic organisms had been added to the toxic infection by saprophytes, an occurrence not uncommon in sapremia. In such cases the reader favors total extirpation to supravaginal amputation, for the reason that the peritoneum can be protected from infection by approximate safeguards.

In cases of septic infection the author had based his blood investigations entirely upon smear preparations, obtained from a finger, and these were unsatisfactory. In 2 instances when streptococci were finally found, previous examination having proved negative, the patient succumbed. In 3 successful instances, in which indication for operation was based on clinical conditions, the blood examinations were negative, the second alone showing streptococci. It would not, in his opinion, be just to the patient to wait always for operation until positive evidence was found in the blood. The writer then mentioned a case which had occurred in his consultation practice in 1893. He had seen a patient three weeks after delivery who had shown all the symptoms of acute septicemia. The physician had not curetted, but relied solely on vaginal douches, stimulants and quinine. When seen by Dr. Boldt, the patient was greatly emaciated, temperature 103°, pulse 124 and feeble. There was no exudate in the pelvis, but the uterus was large, boggy and sensitive to touch. Examination of the interior of the uterus did not reveal the presence of placental tissue. After the examination the patient had a severe chill, temperature rose to 105.8°, pulse to 156. In view of the gradual sinking of the patient, the irregular chills, fever, the size and consistency of the uterus, the condition was diagnosed as septic metritis, and hysterectomy performed the following morning. The diagnosis proved correct, the tissues of the uterus tearing as if decomposed. The patient had no more chills, the highest temperature after the operation was 101°, and recovery was uninterrupted. Under similar conditions, even with a negative result of blood examination, the writer would adopt the same course today.

It is impossible with our present knowledge to lay down absolute rules for the performance or omission of the operation of hysterectomy, but for general guidance, I would advise the following indications for hysterectomy, if it is evident that less heroic treatment is useless:

(1) If after a full term delivery, or an abortion, there are no conception products in the uterus, and the patient has fever with exacerbations, chills, a small and frequent pulse (120 to 140 or more); if careful observation should show that the infection comes from the uterus alone, that organ being enlarged, and relaxed in its consistency; if there is no evidence of peritonitis, the parametria free; if streptococci are found in the uterus, and, especially, if the blood shows the presence of pathogenic germs.

(2) If there are decomposition products in the uterus, as in the instances reported by Schultze, Prochownik, Stahl and others, which cannot be removed satisfactorily per vaginam; if on doing a Cesarean section the uterus is found septic, then an abdominal hysterectomy is indicated.

(3) Abdominal section with drainage is indicated in diffuse septic peritonitis, when there is no evidence of an exudate in the pelvis.

(4) The adnexa are to be left undisturbed unless there is a positive indication to do otherwise.

In the discussion DR. VINEBERG said that he agreed with Dr. Boldt in his indications for hysterectomy, but that he personally preferred the abdominal route to the vaginal. He could not agree with the reader of the paper with regard to the definitions of sepsis. He thought there were no grounds for the introduction of the term bacteriemia. To his mind there was but one kind of infection. Many times, from neglect, putrid intoxication runs into acute septicemia, and the profession should be taught that each case of sapremia is one of septic infection from the onset, and that it may pass into acute septicemia. Infection with other bacteria, such as the bacillus coli communis, the staphylococci and the bacillus aërogenes capsulatus, have also been attended with fatal results.

DR. STONE congratulated the reader of the paper on his successful effort to pick out and define the different varieties of puerperal infection. To his mind, the profession was too apt to think that there was only one form of sepsis, and that the correct thing to do in each case was to curette. This he thought a great mistake, as many cases get well without curettage.

DR. BROTHERS thought the question of treatment depended upon the recognition of the presence or absence of local infection. This infection may be due not only to placental débris after delivery, but to some condition of local infection occurring previous

[1] Deutsch. med. Wöch., 1886, No. 44.
[2] Centribl. f. Gynäk., Bd. xvii, S. 667.

to delivery. He agreed with Dr. Boldt that if the diagnosis of acute bacteriemia can be made, hysterectomy or any other form of local treatment is contra-indicated. In his opinion, the terms "local sepsis," "acute bacteriemia," and "chronic bacteriemia" were well chosen.

DR. W. E. PORTER said he believed that many cases would not come to hysterectomy if persistent intra-uterine irrigations were properly carried out. In his experience the placental forceps were much better than the curette for the removal of retained secunda.

DR. MALCOLM MCLEAN had seen several cases in which lactation had given symptoms severe enough to make one strongly suspect septic infection, and he advised the greatest caution in making the diagnosis which would result in the performance of hysterectomy.

DR. G. L. BRODHEAD referred to those cases of hysterectomy for retained placenta which Dr. Boldt had reported, and said that, in his opinion, if retained placenta could not be reached by the usual methods, it would be better to incise the cervix in order to get more space in which to operate. Certainly the greater part of retained placenta could be removed in this way, and therefore hysterectomy would never be indicated.

DR. JANVRIN said he had never attempted to remove a uterus for acute septicemic action, but that he should like to ask Dr. Boldt to tell how one should know whether to perform abdominal or vaginal hysterectomy.

DR. BOLDT said that he would again refer to the excellent definition given by Coplin under the term "mycosis of the blood." We must recognize the fact that puerperal fever is always in a degree a septic infection. If fetid discharges come from the vagina, it does not necessarily mean that the case is a serious one. Patients with acute bacteriemia may have no fetid discharge, and yet there may be an intense septic endometritis. We must watch our cases for a number of days or several weeks, and if we find that all treatment has failed, the patient is steadily getting worse, no other cause for the chills, etc., can be found, where the parametria are free, and there is no peritonitis, where perhaps streptococci are found in the uterine secretions, then, under these conditions, we are justified in considering vaginal hysterectomy.

Abdominal hysterectomy should be considered only in cases where we are called on to perform a Cesarean section on a septic uterus, or where there is an intense septic intoxication associated with a septic endometritis, the patient's condition not improving under other treatment.

The reason why the placenta could not be removed in the case reported by Schultze was on account of there being a uterus bicornis. In the other case, quoted from Sippel, the general condition of the patient was such that it was not advisable to carry on intra-uterine manipulation further, so great was the danger of perforation.

In conclusion Dr. Boldt said that it required great judgment to decide in these cases what was correct to do, but that each must judge from his own experience with the aid of all the symptoms present. We should all endeavor to make exact definitions of the diseases that we are dealing with.

THE BOSTON
Medical and Surgical Journal

THURSDAY, FEBRUARY 28, 1901

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE NEEDS OF A MEDICAL LIBRARY.

SINCE the Boston Medical Library moved into its new building on the Fenway, a number of suggestions have been made looking toward improvement of the advantages it already offers the profession.

The most important improvement, after all, must consist in the extension of the book collection, and it is with a view to the possible strengthening of the collection where it is still somewhat weak that we venture to call attention to the fact that books may not only be given to the library, but may also be deposited as loans, under good care and without risk of loss.

The library should be in the future even more than in the past both the place for systematic study of medical literature, and the place where it may be convenient for the medical men to drop in, to skim over current journals or look up a given subject or a given point with the least possible loss of time.

To admit of this requires a reasonably complete representation of the total information in various lines of work, — not only the journals, archives and annals, but also those monographs and books of reference which from time to time condense the scattered information of the periodicals in quickly accessible form.

The Medical Library, through the quarter century of its existence, has especially striven to present contemporaneous literature. In this it has been, as we all know, notably successful. During this period many books other than periodicals have been collected (nearly 15,000), but the collections of special works and books of reference are still somewhat deficient.

In the past the limited funds of the library have not allowed any considerable purchases, and the lack of accommodations has not encouraged gifts. The lack of funds continues, the more felt owing to the expenses incident to the change of quarters, and the library cannot, for the present at least, set aside any adequate fund for the purchase of books; can, in fact,

do little more than keep up its periodicals. Today, however, there is no lack of room or of facilities for keeping and handling books.

Undoubtedly the library's need will be met to some extent by gifts. Special libraries have been presented; there are already two funds to provide for purchasing special classes of books, and one of the specialists' clubs is now considering the question of helping to keep up the shelves representing its specialty.

But apart from this there is an opportunity for individuals to give valuable aid with a minimum of self sacrifice. Hundreds of volumes that the library does not possess lie unused on the shelves of private individuals. Many medical men, too busy to be bibliophiles, buy sets of reference books or send for special works or monographs, and after the present need for them has gone by rarely look at them, often hardly know where they are.

The library is ready and anxious to receive such books, not only as gifts, but as loans, to keep them safely, and, if need be, to restrict or prohibit their circulation as the owner may desire. In this way the owner can share with others what he little uses, and his books will be safer and in many cases more accessible, even to him, than if they lay unclassified, uncatalogued, on his own shelves.

It is not supposed that whole libraries will be so deposited, but it is hoped that this suggestion may lead to the depositing of many single volumes and sets not now in the library and not accessible. If this suggestion bear fruit and be responded to, many gaps in the present collection will be filled and we shall all be the richer in opportunity to learn. It is a chance to cooperate in the furtherance of a cause with which all are in sympathy.

GOOD BREAD AND SANITARY BAKERIES.

It is scarcely necessary to state that bread is one of the most important, possibly the most important, of all articles of diet. Its universal use, on all occasions, and at every meal, by all classes of people makes it imperative that it should be made not only of wholesome materials, but also under strict sanitary conditions. In 1896 a statute was enacted in Massachusetts providing for the regulation of bakeries, with special reference to their sanitary conditions, and placing them under the supervision of local boards of health. This legislation was a step in the right direction, but an important provision was omitted, to which considerable attention has been paid in the sanitary investigations of other countries, — the provision that no bakery shall be maintained in an underground room or apartment. It is quite clear that the important sanitary conditions of good ventilation, light, dryness and perfect drainage can never be so well secured below the surface of the soil as above it, and all these conditions should be maintained in a good bakery. This question has provoked lively discussion in English journals, as is shown by the following extract from the *Local Government Chronicle*, London, February 2d:

Scarcely a week passes that we are not called upon to part with one or other of our most cherished illusions. We have long known that typhoid lurks in water, milk and shell fish, but until recently few of us suspected that we were drinking arsenic in our beer. Still fewer of us have as yet regarded our daily bread with suspicion. We have been taught from our infancy that bread is "the staff of life," and it is, therefore, somewhat disconcerting to learn that Drs. Waldo and Walsh have cultivated thirteen different species of microbes from newly-baked London loaves, and that Surgeon-Major Rennie has traced two outbreaks of typhoid fever amongst our soldiers in India to the agency of bread baked in the native bazars. It is no new thing for us to hear that the majority of our urban bakehouses are underground; that they are very dirty and insanitary, and that the journeyman baker has a very bad time in them; but the majority of us have derived some satisfaction from the reflection that, bad as its surroundings might have been, and serious as might be the discomforts of those engaged in its production, our loaf has been purified by fire before it reaches us. If, however, the statements made in *Fabian Tract*, No. 94, entitled "Municipal Bakeries," and published last month, are to be relied upon, we can no longer feel assured that this is the case. So far we have not heard of any authentic case of disease having been communicated by bacteria from bread in this country, but several sanitary experts seem to be of opinion that insanitary bakehouses, of which we have long known there are a considerable number in all our large towns, constitute a source of danger to the public health, which it is very desirable to remove. The medical officer of health for Manchester is "strongly of opinion that the time has come when a period should be put to the existence of cellar bakehouses." Without fully endorsing this opinion, we fear there can be little doubt that sufficient attention has not hitherto been paid to the sanitary condition of urban bakehouses, and to the miserable condition of many of those who work in them. Most of us would prefer that our bread was made in clean rather than in dirty bakehouses, and it is not pleasant to hear that journeymen bakers are rarely to be found above forty five years of age; that from the surroundings in which they work they are bound to suffer from lung diseases and anemia, to say nothing of "baker's itch," rheumatism, erysipelas, and other complaints; that their hours of work are exceptionally long, and that they are specially prone to suicide.

MEDICAL NOTES.

Vital Statistics of Havana for January, 1901. — The sanitary improvement heretofore noted continues during this month. It will be seen that the number of deaths, 476, is the smallest that has occurred in any January in Havana in the last twelve years, the next lowest being that of January, 1890, when there were 486 deaths, the highest being that of January, 1897, when there were 1,556 deaths and an average of 829 deaths. In comparing the death rate, there is a still better showing. The rate for this month, 22.75, is considerably less than the lowest for the past twelve years, 1894 being the next lowest, with a rate of 27.36. Yellow fever has decreased

from 62 to 24, and the deaths from this cause, from 20 to 7. The number of deaths is kept up by the increase among the deaths from tuberculosis, which about balances the decrease in deaths from fevers.

DIPHTHERIA ANTITOXIN INFECTED WITH TETANUS. — According to the *New York Medical Journal*, 20 deaths from tetanus were reported recently in cases which had been treated with a particular lot of diphtheria antitoxin made in Milan, Italy. A rigid governmental inquiry has been set on foot and the antitoxin seized.

DEATH OF PROFESSOR VON PETTENKOFER. — The death of Professor von Pettenkofer, of Vienna, is announced at the age of eighty-three.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, February 27, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 98, scarlatina 35, measles 51, typhoid fever 4.

DEATHS IN BOSTON IN 1900. — There were 11,678 deaths in Boston during the year 1900, an increase of 511 over 1899, and making the death rate for the year 20.82 per 1,000 inhabitants, as against 20.12 for the previous year. Consumption again leads in the total number of deaths from a single cause. There were 3,752 deaths of children of five years and under, which is 32.14% of the total number of deaths reported to the Board of Health for the year.

STATE LABORATORIES AS AIDS TO SANITARY WORK. — Dr. Samuel W. Abbott, secretary of the Massachusetts State Board of Health, read a paper before the Maine Academy of Medicine and Science, January 14, 1901, on the subject of "State Laboratories as Aids to Sanitary Work." Its sentiment received the heartiest approval of the academy, and to express its views upon the subject that body has caused a pamphlet to be printed and given a limited distribution, as a reason why the bill before the present legislature, asking for funds to equip a State laboratory in Maine, should receive favorable consideration.

A CENTENARIAN. — Mrs. Mary Welch, the oldest woman in Pittsfield, Mass., died last week at the reputed age of one hundred and two years. She came of a long-lived race, her father, John Fitzgibbons, dying at one hundred and five, and her mother one hundred and four. Mrs. Welch was born in Kinnaula, County Tipperary, Ireland, in 1799.

A PRECOCIOUS SUICIDE. — It is reported that a boy of thirteen has recently committed suicide in Connecticut, for the alleged reason, as given on a note found in his pocket, that he did not like his teacher, and "didn't want any more trouble."

GRADUATION OF NURSES AT BAPTIST HOSPITAL. — Three nurses have recently been granted diplomas from this hospital. At the exercises held on that occasion, Dr. Hugh Cabot, of Boston, and Dr. Alfred Worcester, of Waltham, spoke.

A POSSIBLE HOME FOR CONSUMPTIVES IN BOSTON. — It is said that certain persons in authority contemplate recommending the use of the Marcella Street Home for incurable cases of consumption.

NEW YORK.

CLAIM OF AN INSURANCE COMPANY UPHELD. — The Connecticut Mutual Insurance Company, in its defence of a suit by Jennie Louis to recover upon a policy issued by it in June, 1895, upon the life of her husband, Joseph Louis, claimed that the policy was void, because Mr. Louis's death, which took place in 1896, was caused by suicide. The policy contained a provision that the company did not assume the risk of self destruction, except upon satisfactory proof that the insured was so far insane as to destroy his responsibility. On the proofs submitted at the trial the jury gave a verdict for Mrs. Louis and that decision has now been upheld by the Apellate Division of the Supreme Court of New York. Justice Ingraham gave a dissenting opinion, holding that there should be a reversal because, in the application for the insurance, facts had been suppressed by the assured which were material in determining whether or not the insurance should be given.

SMALLPOX. — While the public apprehension of smallpox seems to have subsided, the disease has by no means disappeared, and on February 20th no less than 13 new cases were reported. The Health Department officials state that at present they are vaccinating only about 30 persons a day in Manhattan, while a few weeks ago the daily number of vaccinations was 2,000, and they fear a decided increase of smallpox from the indifference of the people. In the town of Woodbury, Gloucester County, N. J., where 3 cases of smallpox have occurred, there is much public excitement. All the Sunday and day schools have been closed by the health authorities, and 4,000 persons have been vaccinated within the past few days.

CARE OF MOTHERLESS INFANTS. — In the twenty-eighth annual report of the State Charities Aid Association, just issued, is given a full report, by the joint committee on caring for motherless infants, in regard to the institutions for children on Randall's Island. Owing to the work of the association, and to new provisions in the rules adopted by the State Board of Charities, the city has been saved over a million dollars during the last five years in caring for its destitute children. The report of the committee on New York County shows many improvements in the charitable institutions in the city and on Randall's and Ward's Islands during the past year.

SANITARY CONDITION OF SING SING AND AUBURN PRISONS. — In his annual report the State superintendent of prisons directs renewed attention to the utterly bad sanitary condition of Sing Sing and Au-

burn prisons, which are now more than seventy-five years old. He states that the evils, which are so serious as to demand immediate attention and prompt relief, if these structures are to be continued in use, have been repeatedly reported to the legislature, but no provision has been made for reconstruction or improvement.

BILL FOR ABOLITION OF PRESENT STATE BOARD OF HEALTH. — The Assembly has passed and Governor Odell has signed the bill providing for the abolition of the present State Board of Health, and substituting for it a single commissioner of health, to be appointed by the governor within twenty days after the passage of the act. The annual salary of the commissioner, who must be a physician of at least ten years' experience, is fixed at $3,500.

CHANGE IN NAME OF MONTEFIORE HOME. — The directors of the Montefiore Home for Chronic Invalids, in order to designate more specifically the work of the institution, have had its name changed to the Montefiore Hospital for Chronic Diseases.

SITE FOR RED CROSS HOSPITAL AND TRAINING SCHOOL FOR NURSES. — The Red Cross Hospital and Training School for Nurses has purchased, for $100,000, a site for a new building at 100th Street, facing the west side of Central Park.

Obituary.

J. H. LINSLEY, M.D.

DR. J. H. LINSLEY died at his home in Burlington, Vt., February 17th, at the age of forty-one, of meningitis. Dr. Linsley is survived by his wife and two children.

He was the only son of the late Hon. D. C. Linsley and grandson of Hon. Jo D. Hatch. He was born at Windsor, Vt., in 1859. He was graduated from the Medical Department of the University of Vermont in 1880, and later was in active practice up to 1887. His health failed about this time, and after a period of recuperation he went to New York City and was appointed instructor in clinical microscopy in the New York Post-Graduate Medical School and Hospital. One year later he was made director of the laboratories of histology, pathology and bacteriology. He was also pathologist to the New York Post-Graduate Hospital and the New York Infant Asylum. In addition, he did the pathological work of St. Luke's and the Presbyterian hospitals, during a part of the summer of 1889. In 1890 Dr. Linsley spent the summer in Berlin and took a course in bacteriology under Koch. He was also English secretary of the Section for Hygiene of the Tenth International Medical Congress held in Berlin in August, 1890. In the fall of the same year he again went to Germany as representative of the New York Post-Graduate Medical School and obtained some of Koch's lymph.

Returning to New York City, he gave the first address on the lymph treatment for tuberculosis in New York in the Academy of Medicine before the Medical Society of the County of New York. Later Dr. Linsley translated "Fraenkel's Grundriss der Bakterienkunde." Later he was made professor of pathology and bacteriology at the University of Vermont, and in some capacity he was connected with the Medical Department of the university for many years. He served as city physician of Burlington for three years, and as health officer for the same period. He was also a member of the Board of Pension Examiners for Chittenden County. On the establishment of the State Laboratory of Hygiene he was made its chief, and in that capacity he had done most useful work.

Correspondence.

[From our Special Correspondent.]

MEETING OF THE THIRD PAN-AMERICAN CONGRESS.

HAVANA, February 13, 1901.

THE third meeting of the Pan-American Congress, held at Havana during the week beginning February 4th, was noteworthy not only for the quantity and high standard of the scientific contributions, but equally for the hospitable courtesies and unique entertainments offered to the delegates by the local physicians, municipal and hospital officials and private individuals. Although the thermometer ranged from 80° to 90°F. during each day, this tropical heat, tempered by the cool trade winds, was made tolerable by the many devices within the houses, streets and *patios* for maintaining shade and the free circulation of air. The nights, moreover, were delightfully cool, and at no time was experienced that suffocating temperature so frequently prevailing in New York and Philadelphia during July and August; while the scrupulous sweeping and washing of all public thoroughfares, formerly so squalid, has served to banish offensive odors. Indeed the cleanliness of the streets, which reminded me of that of Paris under the empire, has proved contagious, so that floors and wainscots, finished invariably in marble, slate or tiles, were rubbed and polished in the various hospitals and institutions until they fairly shone.

In one of the smaller hotels, called Florida, in the Calle Obispo, originally occupied as a private palace, we found cool, clean apartments, good attendance and a most excellent cuisine.

For the meetings of the general sessions and of the sections ample provision was made in the great theatres, Tacón and Martí, the *aula magna* of the University and the lecture rooms of the adjacent Institute of Secondary Instruction. The total number of delegates amounted to about 400, and I heard some disappointment expressed at the rather meagre attendance of less than 80 physicians from the United States. One can safely predict, however, that at the fourth meeting of the congress, to be held in 1903, in the remote city of Buenos Aires, the representation from North America will be even smaller. The language generally employed was naturally Spanish. Indeed, as this is now the tongue of seventeen independent nations of the new world, with whom, as well as with our island colony, Puerto Rico, and the Philippines, we are steadily cultivating more intimate relations, a speaking knowledge of this idiom will soon be of importance to our people and especially to medical men.

An extremely favorable impression was made upon the visitors by the professional attainments and linguistic accomplishments of the Cuban physicians, many of whom, educated in European capitals, at New York or Philadelphia, would take a high rank in any country. The general sessions were presided over with dignity and tact by Dr. Santos Fernandez, an oculist of wide repute, and director of the histo-bacteriological laboratory inaugurated in 1887. The governor-general, Dr. Wood, who had held a reception at the Palace in the afternoon, spoke the opening words of welcome Monday evening, at the Tacón Theatre, and was unremitting, thereafter, in his attentions to the delegates.

At the time of the organization of this congress it was announced that its paramount function would be the study of those intertropical contagious diseases which menace the cities of the temperate zones. Of the many valuable papers on this topic none commanded more widespread

interest than the contribution to the etiology of yellow fever presented at the Section of General Medicine by Drs. Walter Reed, James Carroll, and Aristides Agramonte, assistant surgeons attached to the United States army of occupation. Their experimental demonstration that under strict quarantine, and with all other sources of infection absolutely excluded, 85.71% of all individuals bitten by purposely contaminated mosquitoes (*Culex fasciatus*) were infected, was received by their audience as conclusive and incontrovertible. As a result of these experiments, it is made evident that the specific virus is not directly transferred by the probosces of these insects from one individual to another; on the contrary it seems to undergo a distinct cycle of development within the organism of the mosquito before the latter is capable of communicating infection, and the period necessary for this process of elaboration is put at not less than twelve days. It is believed, therefore, that the danger of contracting this disorder may be virtually avoided by enclosing one's bed with a wire screen, a contrivance which I observed had been adopted by Gen. Lee in his summer palace at Mariano.

Another series of experiments seemed to indicate that articles of clothing and bedding contaminated with the excreta of yellow fever are absolutely incapable of conveying the disease, and hence that the disinfection of such articles is no more necessary than of the *fomites* of malarial fever; a theory too startling to be accepted on the rather limited evidence offered in its support. It is interesting to recall that this view of the propagation of yellow fever by mosquitoes was maintained by Dr. Charles Finlay, of Havana, in a paper based on experimental data which he reported at a meeting of the Havana Academy of Sciences held in 1881. On motion of Dr. Eduardo Wilde, minister of the Argentine Republic to the United States, it was resolved to constitute a Pan-American commission for the scientific study of the methods of propagation of yellow fever wherever endemic, and for the purpose of suggesting concurrent action on the part of all interested nations in carrying into effect such uniform sanitary restrictions as may lead to the suppression and possible extinction of this pestilence. When once this disorder is placed under control in the few seaports which at present constitute the foci of infection, then this continuous source of danger to the cities of North America will cease and a most expensive burden incident to quarantine regulations, disinfection, etc., will have been lifted from our maritime commerce.

At the closing general session held Thursday evening in the Martí theatre, the only paper in English was that on sanitation and quarantine by Dr. Walter Wyman, Surgeon General of the United States Marine-Hospital Service.

On Friday, the 8th, about 300 delegates, with their wives or daughters, accepted an invitation from Señor Pelayo to spend the day on the sugar plantation "Rosario," situated near Aguacate, about forty-five miles from Havana. Arriving at this town we found the entire school population drawn up with flags and banners at the station to receive us. Conveyed thence by private railroad directly to the villa, we were there graciously welcomed by the ladies of the household. After inspecting the cutting of the sugar cane and the large plant where the extraction of its sap and final conversion into sugar were accomplished entirely by machinery, we were conducted to a vast grove. There beneath the shade of a great variety of palm, fruit and other tropical trees unknown to us even by name, we were served an elaborate dinner made up of native dishes and choice wines. The favorite course with the Cubans was *el lechon*, or roast sucking pig, which we also found most palatable. By the nephew of the proprietor I was told that no less than $60,000 was paid to the contending parties during the recent rebellion to secure the preservation of this property from destruction by fire, a fate which brought ruin to most of the neighboring planters.

On the same evening a grand ball was given by the municipal authorities in the Tacón theatre, attended by 7,000 invited guests, representing the beauty, wealth and learning of the metropolis. Music was furnished by a well trained orchestra and large military band, while in the adjacent *patio* were served in profusion ices, *dulces* and wines.

At the reception given on the evening of Saturday to a limited number of delegates by Dr. and Señora Ygnacio Plasencia y Lizaso we had the opportunity of inspecting the interior arrangement of a large private mansion, and were amazed at the elegance, luxury and artistic taste displayed in the extensive offices, operating room and library of this distinguished surgeon, all designed on a scale which elsewhere would be thought adequate for a public institution.

A final excursion made to the province of Matanzas enabled us to visit the caves of Bellamar and the famous Yumurí valley, where we were fairly overwhelmed with acts of courtesy by many of the Cuban teachers whose acquaintance we had chanced to make at Cambridge during the previous summer.

A. H. N.

LITHOTOMY AND LITHOTRITY IN TURKEY-IN-ASIA.

MARDIN, TURKEY-IN-ASIA, January 18, 1901.

MR. EDITOR: In your issue of March 22, 1900, you kindly noticed the "247 cases of lithotomy," quoting from the *Missionary Herald*. You were kind to do me the honor. "Lithotomy" did not give its true meaning. I have since added *eleven* more to my number, and the way in which they are recorded is the way in which I have been dealing with the stone in recent years. I give the name *lithotrity* where I leave the débris to be carried off by the weight of the urine. I find it very suitable in some cases. The lithotomy cases are small children, for whom a small enough lithotrite has not been found.

The last year of the century, as it crowded itself into these regions, found Mardin contending with smallpox and a severe type of measles, worse than had ever been seen or heard of in this city. Its victims were counted by the hundreds, and some say thousands. It certainly was a very virulent form of a disease that they had always been accustomed to look upon as they would a slight cold, that comes and goes while the patient would not lose a meal or a day from his play. But now, scarcely a family but what were called upon to part with one or more of their little ones, some families three or four. No such epidemic of measles has ever been known in these parts. The whooping cough came in as a tailboard to the two preceding scourges, taking not a few of those left over from smallpox and measles.

Then, during the latter months of the year, a severe epidemic of erysipelas spread through the city, extending to the near and distant villages, no class or age escaping. That, too, carried off some of the less robust cases, and as the century unwinds the last coil of its great spring, we find about the only thing remaining of importance — and that is minor — chicken pox.

Notwithstanding the above account of sickness, suffering and death, to a foreign mind it would seem strange that the work of the medical man should be less than when these epidemics did not exist. For smallpox and measles who would call a doctor? They would only be laughed at. But towards the last, when so many were being taken, they began consulting the M.D., but only a few at that, so that on the whole I have a smaller number of cases to record than last year.

The work of the year has been heavy and tiresome, very few capital operations, but a large number of minor cases, requiring as much, or even more, attention than the capital cases. I often had 20 or more dressings a day to do for out patients, aside from the regular hospital cases, the dressings for the year amounting to over 5,500.

The same old story to repeat accounting for the decline in the medical and surgical work of the year — *poverty*, which becomes year by year more acute. A number of capital surgical cases were turned away because they could not

pay the amount asked of them for their stay in the hospital, so they went their way sorrowing at their fate, while we too sorrowed because of our inability to take them in.

Very truly yours,

D. M. B. THOM, M.D.

SHOULD A HOSPITAL CHARGE FOR INFORMATION ABOUT PATIENTS?

BOSTON, February 23, 1901.

MR. EDITOR: — On February 11, 1901, a patient of mine was admitted to the Massachusetts General Hospital. I had attended him about two days previous to his admission and had made a diagnosis of ruptured urethra and extravasation of urine. This diagnosis was concurred in by another physician who saw the case with me. Yet on account of the absence of retention of urine, the peculiar character of the swelling and the absence of other typical symptoms, the diagnosis was not beyond peradventure.

Four days following admission, I requested, by letter, of the superintendent the diagnosis made and operation performed. I received an answer confirming the diagnosis made before entrance, with a statement of the operation performed. Two days later I received a bill for "searching and copying record, $1.00."

Now, Mr. Editor, I consider this preposterous. A hospital of the character of this hospital, that has been generously aided by the State and generously endowed by public-spirited citizens, is not strictly a private institution. The State and citizens endowed this hospital primarily for the aid of the needy sick, and secondarily to educate students and physicians. It would seem a matter of common courtesy and in furtherance of one of its objects to supply this slight information when requested by the attending physician. I should even go further and say that the attending physician should be notified of any intended operation on his case and invited to be present.

It is not the amount to which I object, but the principle.

In view of the enormous advantages granted to the favored few composing the staff, it would seem that this privilege to the practising physician is infinitesimal.

I am pleased to add that the City Hospital has cheerfully and freely furnished such information for which its aristocratic and autocratic neighbor begs pay.

Very truly yours,

W. H. E.

NOTES ON X-LIGHT.

BOSTON, February 23, 1901.

MR. EDITOR: — The only answer I desire to make to Dr. Codman's criticism of my previous communication[1] is embodied in the following statement:

A pregnant guinea pig was placed in a closed metallic chamber hung by silk cords within a closed metallic chamber connected with the ground. This is the same arrangement for excluding electricity as a factor in the results which was used in the other experiments. The source of x-light was outside. Exposure to x-light killed the fetus. I limit the statement of these experiments to one guinea pig, and publish this note because pregnant women are being exposed to x-light to determine the size of the pelvis or to examine the condition of the fetus. I may add that I have known of a woman who aborted after exposure to x-light. What people fear is uncertainty; therefore, when a new agent is employed in medicine it is important to determine its power by experiment on animals. When we know the worst and can control the agent, we need not fear that patients will object to its use. Nothing is gained by criticising such experiments, for criticism is sterile, while experiment is fertile. An experiment can only be discredited by another experiment.

Very truly yours,

WILLIAM ROLLINS.

Newburyport	14,478	5	—	—	20.00	—	—	—
Melrose	12,962	—	—	—	—	—	—	—

Deaths reported 3,054; under five years of age 836; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 680, acute lung diseases 435, consumption 400, diphtheria and croup 92, diarrheal diseases 63, scarlet fever 46, influenza 44, typhoid fever 24, whooping cough 13, measles 8, cerebrospinal meningitis 6.

From whooping cough New York 4, Philadelphia 3, Boston and Somerville 2 each, Baltimore and Quincy 1 each. From cerebrospinal meningitis Worcester and Everett 2 each, Boston and Fitchburg 1 each. From scarlet fever New York 24, Philadelphia and Boston 10 each, Worcester and Medford 1 each.

From typhoid fever New York 11, Philadelphia and Pittsburg 7 each, Boston 2, Lowell, Lawrence, Somerville and Waltham 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,789,099, for the week ending February 2d, the death rate was 16.4. Deaths reported 3,707: acute diseases of the respiratory organs (London) 323, whooping cough 104, diphtheria 69, measles 56, fever 33, diarrhea 30, scarlet fever 30.

The death rates ranged from 10.0 in Burnley to 26.4 in Norwich: Birkenhead 13.1, Birmingham 15.5, Blackburn 13.9, Bolton 14.1, Bradford 17.2, Brighton 15.4, Bristol 15.8, Cardiff 11.8, Croydon 12.4, Derby 11.9, Gateshead 24.1, Halifax 19.5, Hull 13.1, Leeds 16.4, Leicester 10.2, Liverpool 21.9, London 16.1, Manchester 19.6, Nottingham 17.0, Plymouth 17.6, Portsmouth 16.2, Sheffield 16.5, Swansea 18.5, Wolverhampton 19.6.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING FEBRUARY 23, 1901.

R. C. HOLCOMBE, assistant surgeon, detached from the "Glacier," and to duty with detachment of marines at Pollock, P. I.

J. W. ROSS, surgeon, retired, by Special Order, Department of Cuba, February 15, 1901, to report to the chief sanitary officer, City of Havana, for duty.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the society will be held in Sprague Hall, Medical Library Building, 8 The Fenway, on Monday, March 4th, at 8.15 P. M.

Papers: Dr. Fred B. Lund will read a paper entitled, "The Surgical Treatment of Gastric Ulcer, with Report of Cases."

Dr. Arthur T. Cabot, "Idiopathic Abscess of the Kidney."

The committee appointed to consider the formation of an Academy of Medicine will report.

ARTHUR K. STONE, M.D., *Secretary*, 657 Boylston Street.

SUFFOLK DISTRICT MEDICAL SOCIETY, SURGICAL SECTION. — The Surgical Section will meet at the Medical Library, 8 The Fenway, on Wednesday evening, March 6, 1901, at 8.15 o'clock.

Paper: "Diagnosis and Treatment of Renal Tuberculosis," by Dr. F. Tilden Brown Discussion by Drs. F. C. Shattuck, A. T. Cabot, Alfred Worcester and Paul Thorndike.

F. G. BALCH, M.D., *Secretary*, 279 Clarendon Street.

LECTURES AT NEW YORK SKIN AND CANCER HOSPITAL.

A series of nine clinical lectures on "Syphilis" will be given at the New York Skin and Cancer Hospital successive Wednesdays, beginning March 6th, by members of the visiting and consulting staffs.

SARATOGA SPRINGS AS A MEDICAL MEETING PLACE IN 1902.

We have received a communication from a correspondent in Saratoga Springs, N. Y., suggesting that city as a most suitable place for the meeting of the American Medical Association in 1902.

RECENT DEATHS.

SENECA TOBIAS HYDE, M.D., M.M.S.S., of Dorchester, died at Hamilton, Bermuda, February 17, 1901, aged sixty years.

H. B. POTTER, M.D., of Lafargeville, Jefferson County, one of the most prominent physicians of Northern New York, died suddenly on February 17th, at the age of sixty-one.

BOOKS AND PAMPHLETS RECEIVED.

Drug Standardization Again. Reprint. 1901.

British Medical Association, Report of the Anesthetics Committee. July, 1900.

Boston Floating Hospital, History and Report, Season of 1900. January, 1901.

Inguinal Hernia. By B. Merrill Ricketts, Ph.B., M.D., Cincinnati. Reprint. 1901.

Twenty-third Annual Report of the Board of Health of the City of Lowell for the Year 1900.

A Case of Paroxysmal Hæmoglobinuria. By William Judson Lamson, M.D., New York. Reprint. 1901.

Appendicitis. Ventral Hernia following Abdominal Section. By B. Brindley Eads, M.D., Chicago. Reprints. 1901.

Some Remarks on the Plantar Reflex, with Especial Reference to the Babinski Phenomenon. By J. T. Eskridge, M.D., Denver, Col. Reprint. 1901.

Cyclic Albuminuria. By G. A. Sutherland, M.D., Physician to Paddington Green Children's Hospital, etc. London: The Medical Publishing Co., Ltd. 1900.

An Introduction to Physiology. By William Townsend Porter, M.D., Associate Professor of Physiology in the Harvard Medical School. Cambridge, Mass.: The University Press. 1901.

The Syphilis of Children in Everyday Practice. By George Carpenter, M.D. (Lond.), Physician to the Evelina Hospital for Sick Children, London. New York: William Wood & Co. 1901.

Medico-Chirurgical Translations. Published by the Royal Medical and Chirurgical Society of London. Vol LXXXIII. (Second Series, Vol. LXV.) London: Longmans, Green & Co. 1900.

Lupus Healed with Roentgen Rays; Report of a Case. The Treatment of Epitheliomas of the Skin, with Report of Cases. By William Allen Pusey, A.M., M.D., Chicago. Reprints. 1900-1901.

Fifth Annual Report of the Board of Managers of the Springfield State Hospital of the State of Maryland, Sykesville, Md., to His Excellency the Governor of Maryland. October 1, 1900. Baltimore. 1901.

The History of Ancient Gynecology. By W. J. Stewart McKay, M.B., M.Ch., B.Sc., Senior Surgeon to the Benevolent Asylum Maternity Hospital, Sydney, etc. New York: William Wood & Co. 1901.

Charaka-Samhita. (Translated into English). Published by Avinash Chandra Kavira ua, Editor of Charaka-Samhita and of Susruta-Samhita (in original), with commentaries, etc. Calcutta: Saniel & Sons.

Diseases of the Anus and Rectum. By D. H. Goodsall, F.R.C.S. (Eng.), and W. Ernest Miles, F.R.C.S. (Eng.). In two parts. Illustrated. Part I. New York and Bombay: Longmans, Green & Co. 1900.

Studies in Human and Comparative Pathology. By Woods Hutchinson, A.M., M.D., Professor of Comparative Pathology and Embryology in the University of Buffalo, etc. Edited by Dr. Edward Blake. London: Henry J. Glaisher. 1901.

On Some Cirrhoses of the Liver. Being the Lumleian Lectures for the Year 1900, delivered before the Royal College of Physicians, London. By Walter Butler Cheadle, M.A., M.D. (Cantab.). Illustrated. London: Smith, Elder & Co. 1900.

Operative and Practical Surgery for the Use of Students and Practitioners. By Thomas Carwardine, M.S. (Lond.), F.R.C.S., Assistant Surgeon, Bristol Royal Infirmary. Illustrated. Bristol: John Wright & Co. London: Simpkin, Marshall, Hamilton, Kent & Co., Ltd. 1900.

The Essentials of Practical Bacteriology: An Elementary Laboratory Book for Students and Practitioners. By H. J. Curtis, B.S. and M.D. (Lond.), F.R.C.S., late Surgical Registrar, University College Hospital, London, etc. New York and Bombay: Longmans, Green & Co. 1900.

On the Use of Massage and Early Passive Movements in Recent Fractures and other Common Surgical Injuries, and the Treatment of Internal Derangements of the Knee Joint. Three Clinical Lectures delivered at St. George's Hospital. By William H. Bennett, F.R.C.S. Illustrated. Reprint. 1900.

The Present Position of the Treatment of Simple Fractures of the Limbs. An Address delivered in opening a discussion at the meeting of the British Medical Association, held at Ipswich, 1900. By William H. Bennett, F.R.C.S. To which is appended a Summary of the Opinions and Practice of about 300 Surgeons. Reprint. 1900.

An American Textbook of Physiology. By Henry P. Bowditch, M.D., John G. Curtis, M.D., Henry H. Donaldson, Ph.D., W. H. Howell. Ph.D., M.D., Frederic S. Lee, Ph.D., Warren P. Lombard, M.D., Graham Lusk, Ph.D., F.R.S. (Edin.), W. T. Porter, M.D., Edward T. Reichert, M.D., Henry Sewall, Ph.D., M.D. Edited by William H. Howell, Ph.D., M.D., Professor of Physiology in Johns Hopkins University, Baltimore. Second edition, revised. Vol. II. CLINICAL NOTES AND COMMENTS: CANCER OF THE EXTREMITY OF THE COMMON BILE DUCT.

BY ROBERT T. EDES, M.D., BOSTON.

CASES of disease observed in the early anatomical stage, when few if any secondary lesions have developed, are the more instructive clinically and pathologically, as they are less impressive from their magnitude or intensity. This condition may be met with where a small initial lesion is so situated that a slight increase in bulk seriously interferes with some important function, and the consequences are as clear cut and decisive as in a laboratory experiment. In the following case the results cannot have been widely different from what would have come from an antiseptic ligature placed around the common bile duct.

A single woman, aged forty-eight, neither excessively stout nor the reverse, had enjoyed good health up to June, 1898. The appetite and digestion had been excellent. Repeated inquiries failed to disclose anything like attacks of gall stone. She had been in the country riding a bicycle and enjoying herself. One day she came home saying she was very tired and was going to bed. Within a day or two there was a loss of appetite, intense jaundice, and light-colored stools. Neither then nor at any other time was there any severe pain or tenderness on pressure. This condition lasted essentially unchanged until her death. In September there was some swelling of the legs, which later disappeared.

In February she had lost, say, 30 pounds of flesh, and was of a deep yellow color. The abdomen was much distended, and evidently contained considerable fluid. The liver was not to be felt below the edge of the ribs, nor could its dullness be detected there. Neither could the spleen be felt. The urine was scanty, although it had been increased somewhat after taking diuretics. The bowels were somewhat loose from the action of mild salines. The appetite was moderate but not absent, and so far, at least, as the absence of discomfort went, the patient enjoyed and apparently digested her food. The blood showed the red corpuscles a little less than 4,000,000, with the whites in normal proportion and normally distributed. There was no material change under any of the medications employed, including those of a clairvoyant, except that from the beginning of the ministrations of the latter the stools were described as becoming green and then black. That which I saw at this time was of a slaty grey, without any tinge of biliary color, and could have been described as green only under psychic stimulus. With nitric acid it yielded a reddish-yellow fluid, which in its turn gave a bluish precipitate with ferrocyanide of potassium, and was undoubtedly due to iron. The diagnosis received no light from supernatural sources. The pulse was usually in the neighborhood of 100, and the temperature at times a trifle above normal, although it was not regularly taken and charted. There was nothing in the least resembling a biliary fever. The tongue was nearly clean and the breath not offensive.

On April 24th she was tapped, and about 12 quarts of serum removed, which contained a large amount of albumin (2.5% dry), and gave a strong reaction for biliary coloring matter. The legs were a good deal swelled. She had "distressed spells." There had been several times specks and streaks of blood in the stools and sputa, and also some epistaxis, but never any severe hemorrhage. After this first tapping it was noted that palpation through the relaxed abdominal walls revealed nothing, but after the second, sixteen days later, there was to be plainly felt below the ribs what was supposed to be (and was) the liver, with the rounded end of the gall bladder below it. The projection of the liver increased somewhat, and after successive tappings its edge could be grasped through the relaxed abdominal wall by the hand for quite a distance without pain, and almost without the notice of the patient. There were in all eighteen tappings, about 12 or 14 quarts being drawn each time, the intervals gradually decreasing.

In September, the patient was seen by Dr. Arthur Cabot, with a view to the (very remote) possibility of painless impaction of a gall stone, and an operation was decided against.

Death occurred on October 15th, after nearly a week of diminishing consciousness and, at the last, convulsions, that is, sixteen months after the first symptoms.

The urine throughout was very deeply colored with bile, of high specific gravity, containing either no albumin or a mere trace, with a few casts, hyaline and epithelial. There was at one time a deposit of rather unusual crystals, consisting, as I was informed by Dr. Wood, of phosphate of calcium. Its quantity used gradually to diminish until a tapping, when for a number of days it was more abundant.

Autopsy took place twenty hours after death. Body was extremely emaciated. A pailful of fluid was found in the abdominal cavity. There were no adhesions in the neighborhood of the punctures, but a few slight ones between the liver, spleen and diaphragm. The omentum was much emaciated. A few flocculi of recent lymph were on coils of intestines and abdominal walls. Kidneys were normal. Spleen was a little larger than the average, but not soft.

There was nothing abnormal in the external appearance of the stomach or intestines. The gall bladder was enlarged, containing many gall stones, pearly white, angular, with colored tips. The interior was yellowish brown in the centre, growing gradually lighter toward the outside. They were largely cholesterin. The fluid contents were greyish and viscid. The lower part of the gall bladder was adherent to the neighboring liver substance, and could not be separated from it except by cutting. The cystic duct was not followed down to the junction. The biliary passages were enormously dilated within the liver, and also the

hepatic and common ducts, down to a point 2 inches from the duodenum where there was an abrupt narrowing. Below this point there was some dilatation but much less extreme. At the point of narrowing there was a small rounded tumor, the size of a medium bean, in or closely attached to the wall of the gall bladder between it and the hepatic duct, and pressing upon the latter. Further down there were some dense portions of tissue seeming on section much like cicatricial. The substance of the liver after the emptying of the ducts was flabby, and very dark-greenish brown. Its firm rounded feeling during life was evidently due to its distension by bile in the dilated ducts. The duct and substance of the pancreas were healthy.

The specimen was given to Dr. R. M. Pearce, at that time of the Harvard Medical School, for microscopic examination. He reported that there was a carcinoma of the papilla at the orifice of the common duct, and a lymph node in the immediate neighborhood. The cancer was very slight in amount, and might easily have been overlooked or mistaken without the microscope. In fact, the primary growth was overlooked at the autopsy and the lymph node supposed to be the primary. The whole amount of tissue involved was hardly as much as the last joint of one's finger.

Although this location of cancer is stated by many monographists to be very rare, a number of cases have been collected from the more easily accessible medical literature, periodicals, and especially from inaugural theses.

There is but little doubt, however, that cancer of the bile ducts is in reality somewhat more common than would appear from the older statements, and that many cases which would have been described as "obstruction" even so lately as fifteen or twenty years ago, have been brought by more careful microscopic methods under the head of carcinoma. This is rather interestingly shown by a comparison of titles in the earlier and later series of the "Index Catalogue" of the Surgeon-General's Library.

TITLES.	1ST SERIES UP TO 1881.	2D SERIES, 1881 TO 1897.
Bile ducts, obstruction and dilatation of.	7 dissertations, 2⅛ column references.	6 dissertations, 1 column references.
Bile ducts, cancer of.	1 dissertation, ⅛ column references.	7 dissertations, 1¼ column references.

In a case which I saw some sixteen years ago, a man aged seventy-six, of simple habits but (supposed) gouty diathesis, had jaundice for forty-five days, with very dark urine and clay-colored stools. The liver and gall bladder were felt below the ribs. My diagnosis was, "probably cancer of the liver with a possibility of simple jaundice (that is catarrhal)."

At the autopsy the bile ducts were all enlarged down to a point about ¾ inch from the opening into the duodenum, where there was a sudden narrowing, and the duct was very small for the remainder of its course. In the neighborhood of the stricture the tissues, adipose and fatty, were somewhat consolidated and nodulated. There was no distinct new growth, either here or in the liver. There is no record of a microscopical examination, but it is quite as likely that this was an unrecognized cancer as that it was a piece of cicatricial tissue, for the existence of which no cause could be found. Cicatricial stenoses have been found in other cases, but usually with them an indication of the causative lesion in the form of an old ulcer.

There are three points at which the bile ducts are especially liable to be affected by cancer, although it may occur in the intervals between them. These are the union of the ducts from the two lobes of the liver, the union of the cystic and hepatic ducts, and the entrance of the hepatic duct into the duodenum. Of cases in which the lesion has been found in the last-named region, that is, at the papilla or a very short distance above it, I have looked up 22, including a number also given in Musser's table.

As to the frequency of cancer in the ducts and of the papilla in particular, the following figures may be of interest. Musser gives 18 cases, of which 9 were in or near the papilla, as against 100 of the gall bladder. In Villard's monograph (1871) are collected 24 cases of cancer of the ducts, of which 1 may have been in this position. Dieckmann[1] says that in the reports of the Munich Pathological Institute, from 1854 to 1884, he finds only 1 case of gall bladder cancer recognized as primary, but 71 of cancer of the liver. Howald[2] says that in the last fifteen years, at the Pathological Institute at Bern, there were 10 cases of primary gall bladder cancer. As both of these last theses were upon "cancer of the common duct," it is fair to suppose that if the authors had found accounts of any cases beside those upon which they based their theses they would have been reported. Kelynack (1897), after the remark that primary malignant disease of the bile passages "although far from common, can hardly be considered rare," states that, "in an extensive search through our pathological records (Manchester Royal Infirmary) of 4,578 cases, I can only find details of 8 clear cases of primary cancer of the gall bladder and 2 undoubted cases of primary cancer of the common bile duct."

The presence of gall stones in connection with primary cancer of the bile ducts and gall bladder is very interesting, in connection both with diagnosis and etiology, and as having a bearing on the origin of cancer in general. Considering the great frequency of gall stones, it is certainly fair to assume that in a certain number of cases their occurrence with cancer is a coincidence. In others, of which the one just reported is one, the deposition of the concretion is much more probably the result of the retention in the gall bladder of what is at first bile, but afterwards becomes considerably altered by a partial absorption and the secretion of mucus.

In this case the stones were small and angular,

[1] Inaug., Thesis, Munich, 1889.
[2] Inaug., Diss., Bern, 1890.

without being facetted, as if they had never been disturbed or subjected to friction. Their color in the interior was dark brown, with thin successive layers of lighter yellow, and externally a pearly white, as if they had been deposited from a menstruum, at first dark, becoming lighter, and at last white, like the fluid in which they were found. This undoubtedly took place after the duct was occluded, the bile originally contained therein having undergone the usual changes. Had they been the cause of the cancer and the stoppage, there was no reason why they should not have been throughout of the usual dark color. There was no stone in the common duct nor in the immediate neighborhood of the new growth.

The theory of the origin of cancer in a local irritation certainly receives support from many cases where gall stones are found in the midst of malignant growths, where they may have been the source of that long-continued but not very intense mechanical irritation, which seems, if any, to be the kind necessary to the formation of a neoplasm. This, however, is far more common in the gall bladder than in the bile ducts. Thus Musser, in 100 cases of cancer of the gall bladder, found stone mentioned 69 times and supposes that it may have been overlooked in many more. On the contrary, in 22 cases mentioned above of cancer of the papilla, or a very little above it, including some of those already tabulated by Musser, gall stones are mentioned 4 times, 3 at least of these being in the gall bladder. The possibility has been suggested that a stone may find a lodgment long enough to set up the necessary irritation, and then escape, without leaving behind definite traces. One case of Leith[8] lends some support to this view. A patient had had definite symptoms of gall stones. None were found at the autopsy, but there was a malignant adenoma, and the walls of the duct were roughened and thickened as if from catarrhal inflammation resulting therefrom. Quinlan (quoted by Kelynack) mentions a case of cancerous disease of the liver where the duct was imbedded in a mass of malignant growth, but its opening into the duodenum was four times the normal size, and suggested the likelihood of passing of gall stones.

To suppose, however, that this is an adequate explanation of the origin of cancer in the papilla or higher up, in any considerable number of cases, is working a mere hypothesis very hard in the face of a large number of cases, in fact in nearly all, where there have been no symptoms whatever of the presence or the passage of gall stone.

The further assumption of a painless passage to cover this gap involves the contradiction of an almost universal rule that the movement of a gall stone through a previously undilated duct is one of the most painful processes which ever takes place in the body. The records of the Dorchester Medical Club mention 2 cases where, death having apparently taken place from the pain and shock, a gall stone was found protruding from the papilla into the duodenum, that is, at the very point where this theory demands that they should escape without pain, but leaving behind them a neoplasm. The observation of Musser that, unlike cancer of the gall bladder which, as well as gall stones, is more frequent in the female, that of the bile ducts occurs with equal frequency in both sexes, also points to the conclusion that while it is very probable that gall stones play an important part in the etiology of cancer of the gall bladder we must look elsewhere for the local irritation necessary to set up a similar growth in the ducts.

The diagnosis of these small neoplasms, lying as they do in a region where they are inaccessible to palpation, is stated by some authors to be almost impossible. This is undoubtedly true as regards their exact size and location, but an approximate diagnosis, such as can in many cases be made with some accuracy, is not without its practical value. I think that every one of the several physicians who saw this case, even in the early stage, formed at least a mental diagnosis not far from the truth as regards the nature of the disease, but I think also that all of them, including myself, would have expected a more extensive lesion to be found at the autopsy after more than a year's growth.

A rapid, complete, non-febrile jaundice in a person over forty or forty-five, preceded and accompanied by no severe and painful paroxysms, and succeeded, if by any, only by a moderate amount of diffuse pain and tenderness, especially after it has lasted long enough to exclude catarrhal jaundice, is an adequate basis for a highly probable diagnosis of cancer of the ducts; and if later the smooth non-nodular edge of the liver, with the gall bladder tense but not tender, presents below the ribs, it is also highly probable that the lesion of the ducts was the primary.

Unfortunately the presence of painful paroxysms is not so decisive in one direction as their complete absence is in the other, for even if significant of gall stones this does not exclude carcinoma.

The distinction between a growth originating in the walls of the duct itself and a small malignant or other tumor in the head of the pancreas pressing upon it, and producing total occlusion there before giving rise to symptoms elsewhere, would certainly be very difficult to make. When the pancreatic disease is more advanced, many of the symptoms are likely to resemble those arising from the bile ducts. The presence of such a tumor must be an extremely rare condition, much more so even than any we have been considering, and when the disease is more advanced the deep seated pain and tenderness, the gradual onset of the jaundice, a hard immovable tumor in the median line, would be likely in most cases to decide the matter. The presence of fatty stools would of course have great diagnostic value, but as this is usually insisted on rather from physiological theory than from clinical observation, its absence throws no light upon a doubtful case, and the same may be said of sugar in the urine.

Of course the important point is to determine as early as possible the exact location of the growth, and this certainly cannot be done without an operation. This has, of course, often been done and

[8] Transactions Medical Chirurgical Society, Edinburg, 1895-96.

successfully for the diagnosis and relief of gall stone.

Musser in his last case[4] had in contemplation an operation for cancer which was for special reasons postponed a few days, during which the patient was suddenly attacked by a fatal hemorrhage. Had this operation been performed it would have been the first to be based upon a distinct diagnosis of cancer of the biliary ducts. It can hardly be doubted that in the future exploratory operations will be undertaken with the object distinctly in view of dealing with a cancer, if such shall be found, either by removal or by circumventing the obstruction in such a way as to give a more or less extended relief.

So far as I am aware the only operation as yet done for the removal of a cancer of a bile duct was that reported by Dr. Halsted,[5] and doubtless familiar to readers. Although not successful as to its ultimate result, it shows the feasibility of such an operation, and the return of the disease after the very careful removal only emphasises the fact, already only too well known, that it is almost impossible to cut wide enough of any focus of cancer to be sure of having included the utmost limits of the infected region.

At the time when the question of operation was formally considered in the present case, it certainly could not have been successful, but had it been possible a year before to have known exactly the condition, it might perhaps have been feasible as in Dr. Halsted's case, and either relief or permanent cure obtained according to the presence or absence of cells of carcinoma beyond the limits of the operation. Considering, however, what must have been the very slow growth, when even after sixteen months the primary and secondary growths together were so small, and yet, as it seems, so far beyond the bounds of a possible thorough removal, it is by no means improbable that even when the first symptoms appeared there must have been a wider diffusion of the new growth than would have been apparent or accessible to the knife.

This case exhibits without any complication the effects of suppression of the bile flow, and does not show the effects usually attributed to its reabsorption, which so far as coloring matter is concerned evidently took place freely. It is to be regretted that no examination of the urine for bile acids was made. I have not found any statement of such an examination having been made in any of the cases closely resembling this. There was not the slow pulse supposed to follow the ingestion of cholic acid, it having been usually not far from 100. There was no delirium until the last few days, no disturbance of the intellect nor excessive depression. It would appear from this and similar cases that the evil effects of long-continued obstruction to the flow of bile are due not so much to its presence in the circulation, as to its absence from the intestine and a consequent steady and fatal impairment of nutrition. Hence the inutility, so far as promoting recovery, of tapping the gall bladder and establishing a fistula, although such a procedure would in cases where the cystic duct remains permeable, remove the effects of reabsorption such as the liability to hemorrhage and to sepsis, which is likely to take place if any ulceration occurs.

In case the only obstruction should be situated near the mouth of the duct, the cholecystenterostomy suggested by Mr. Robson would relieve both sets of symptoms until the growth of the neoplasm made another invasion higher up, and in the case of a very slow growth, such as there may be, such a temporary relief might add a considerable time to life.

An operation for establishing an anastomosis between the common bile duct and the duodenum is reported by Dr. J. E. Summers, Jr., of Omaha,[6] but without details as to the anatomical condition before operating, especially the nature of the stricture. He speaks as if the getting rid of the bile were the chief object in making the communication, and as if it were to be undertaken only when the discharge cannot be secured through the gall bladder. The supply of this digestive fluid in the intestines, which cannot be supplemented by any other, is of equal importance, and more details as to this case would certainly be very interesting.

The bibliography of the subject may be found largely in the "Index Catalogue" of the Surgeon-General's library, but it is useful to call attention to four important articles not to be found there. The elaborate study by Dr. Musser in the *Transactions of the Association of American Physicians* for 1894 is not there, probably for the reason that it is to be indexed under the title "Gall Bladder," although it is equally complete on the subject now under consideration. There is a subsequent paper of his in the *Philadelphia Medical Journal* for October 6th of last year. The largely statistical article by Kelynack is to be found in the *Medical Chronicle* (Manchester), and is a very important one. Fourthly, come the article[7] and book (1897) of Mr. Robson on the "Surgery of the Biliary Passages."

THE INTERPRETATION OF BACTERIOLOGICAL FINDINGS IN DIPHTHERIA DIAGNOSIS.

BY HIBBERT WINSLOW HILL, M.D., BOSTON,
Director of the Boston Board of Health Bacteriological Laboratory.

IN May, 1898, the examination of diphtheria cultures for the city of Boston was transferred from the Harvard Medical School to the laboratory then just established by the Board of Health in the Sudbury Building. For about three years prior to that date this work had been under the direction of Prof. H. C. Ernst. On him fell the trials and difficulties always inseparable from the introduction of new methods and procedures. Having successfully met and conquered these, he

handed the work over at a time when its value was established, and it had become a recognized factor in the always difficult subject of the management of diphtheria cases.

Only two changes of any moment were made in the diphtheria diagnostic service; one technical (the substitution of the now almost universal "swab" for the platinum wire), the other executive (the requiring of two consecutive negative cultures for release instead of one). In May, 1900, a further executive change was made in requiring that each of the two consecutive negative cultures for release should be taken from both the nose and throat of the convalescent patient.

SUMMARY OF EXAMINATIONS.

The official year ends January 31; therefore, the diphtheria work of this laboratory since May, 1898, may be conveniently divided into three periods: the first representing nine months of 1898-1899, the second and third periods corresponding with the two following years to January 31, 1901. The following table shows the main features of the work:

	Cultures Examined.				Persons Examined.				Diph. cases in city*
Year	Month av.	For D.	For R.	Total	Month av.	Pos. D.	Neg. D.	Total rel'd	
	1	2	3	4	5	6	7	8	9
1898 9 mos. actual	440	1,544	2,404	3,948	190	321	1,148	415	
est. 1898	440	2,000	3,200	5,300	190	400	1,500	550	1,661
actual 1899	660	4,408	3,522	7,930	380	1,019	2,920	1,002	2,836
approx. 1900	1,560	8,000	10,800	18,800	700	2,100	5,600	2,000	5,020

* Cases reported.

It will be seen (column 9) that the number of diphtheria cases reported in the city increased about 75% each year over that of the year before during this time. The monthly average of persons examined (column 5), naturally increased also. Some of these examinations were compulsory, that is, due to the regulation of the Board requiring cultures *for release* from persons convalescent from diphtheria. The examinations made *for diagnosis* are wholly voluntary however, and it is satisfactory to see that the number of persons thus examined (columns 6 and 7) have increased at the rate of about 90% to 100% each year.

The most satisfactory increase is that shown by comparison of the total diphtheria cases reported (column 9) with the total positive cases examined for diagnosis at the laboratory (column 6). It will be seen that in 1898, the positive laboratory diagnoses were but 25% of the total cases reported; in 1899, they were about 35% of the total cases reported, and in 1900 about 42%, holding out the hope that the majority of the cases reported in the future as diphtheria will pass through the laboratory for examination.

Comparison of column 8 with column 9 shows that from 33% to 40% only of the total cases reported are released by this laboratory. The remaining cases are accounted for by the large number of "removals to hospital" (50 to 60% of the total cases) and by deaths.

INTERPRETATION OF RESULTS.

The meaning of a positive report.— When a physician receives a positive report on a culture sent in from a doubtful case he is sometimes puzzled to know exactly what diagnosis to base upon it, and is sometimes not clear as to the status of such a patient in the eyes of the Board of Health. If the positive report coincides with such a clinical condition that the physician is satisfied of the presence of the *disease of* diphtheria, no trouble arises. If, however, the positive report is made on a patient whose clinical condition is not that which the physician is accustomed to regard as the disease of diphtheria, the physician may either yield but doubtfully to the laboratory report or may dispute its correctness.

At the bottom of much of the trouble found in adjusting laboratory reports to clinical diagnoses of disease lies the fact that the definitions and nomenclature of bacterial diseases are yet in a state of flux. Agreement in diagnosis can never be reached by two men whose definitions of the disease in question differ essentially.

That form of definition and nomenclature based on cause, as distinct from anatomical or physiological character, is every day becoming more and more used in all forms of bacterial disease.

Tubercular meningitis and chronic consumption are totally different diseases clinically. But no one hesitates now to class them together on the basis of cause — the tubercle bacillus. Such a basis of classification is more useful and rational than a merely clinical basis, since it allocates more correctly the ultimate processes of disease as well as important relationships of these to complications, sequelæ and infectiveness.

It must be remembered of course that bacteria as such are not themselves the immediate cause of disease. A pathogenic bacterium is pathogenic only through the poisons it may but does not always produce; moreover the body forces tend to neutralize these poisons when they are produced.

The definition of any specific bacterial disease may be stated therefore very broadly, as *the reaction of the body to that portion of the specific bacterial toxins which the body fails to neutralize or eliminate.* Under this definition the disease of diphtheria exists always, and exists only, when the body shows a reaction to toxins formed by the diphtheria bacillus. This definition does not require that the reaction of the body to the toxins shall be along fixed clinical lines. Indeed, poisoning by diphtheria toxins does not invariably result in such fixed conditions. All gradations of the systemic poisoning may be recognized and a variety of anatomical conditions may accompany these. The relation of the various common types

of "sore throat" to each other under the older and the newer conceptions of the disease may be roughly shown thus:

OLDER ANATOMICAL CLASSIFICATION.	CLASSIFICATION ON BASIS OF CAUSE.
Membrane = diphtheria	Membrane due to diphtheria bacillus toxins = diphtheria.
	Membrane not due to diphtheria bacillus toxins = not diphtheria.
Exudate = follicular tonsilitis	Exudate due to diphtheria bacillus toxins = diphtheria.
	Exudate not due to diphtheria bacillus toxins = not diphtheria.
No membrane or exudate = simple sore throat	Simple sore throat due to diphtheria bacillus toxins = diphtheria.
	Simple sore throat not due to diphtheria bacillus toxins = not diphtheria.

The difficulty of working under this definition and classification of diphtheria is that it makes the presence of the disease depend on the presence and activity of diphtheria toxins, while no absolutely decisive method for determining the presence and activity of the toxins is at hand. It is true that, if marked symptoms of diphtheria poisoning develop the physician may accept as demonstrated both the presence of the toxin and its activity, that is, the absence of its neutralization; if no symptoms at all develop he is sure that the toxins were not formed, or if formed were neutralized — it does not matter which so far as the patient is concerned. This clinical test is, however, likely to be spoilt, or at least seriously interfered with, by treatment, especially if diphtheria antitoxin be employed — the very symptoms to which the physician might look forward for confirmation of his earlier tentative diagnosis being often thus made of no avail from the diagnostic standpoint. Finally even the developed symptoms may be of an indecisive character.

The determination of the presence of the diphtheria bacillus is therefore used as a sort of "toxin-indicator." It is true that the diphtheria bacillus may be present and yet no toxin be formed, for the diphtheria bacillus does not always produce its poisons. It is true that the diphtheria bacillus may be present and may be producing its poisons, and yet that the body forces may neutralize them as fast as they are made. In both these cases a diagnosis of diphtheria based on the presence of the diphtheria bacillus alone must fall to the ground, since in neither case will the body show a "reaction to diphtheria toxins" as required by the definition given.

Animal experiments may demonstrate the presence or absence of toxin-making power in the particular diphtheria bacilli isolated, but such a laboratory test is too slow for use in diagnosis, besides leaving undetermined the equally vital question of whether or not the diphtheria toxins are being neutralized by the patient. This latter point can indeed be decided only if at all by the condition of the patient, who is himself at once a combined "test for virulence" and for "neutralization of toxins."

Diphtheria diagnosis by culture, therefore, is based on a definition and some assumptions. We must admit that diphtheria is that disease, whatever its precise form, which is caused by diphtheria toxins. We must assume that if diphtheria bacilli are present, the diphtheria toxins are present also. We must assume that if diphtheria toxins are present, any symptoms presented by the patient are due to those toxins.

In the great majority of cases, these assumptions, always legitimate in the absence of evidence to the contrary, prove correct. Being based on generalizations, however, they will sometimes fail in particular cases, but the percentage of failure is much less than that of unaided clinical observation.

The relation of the Board of Health to the patient showing a positive culture is comparatively simple. The Board of Health does not take the position, as may be gathered from the foregoing discussion, that a sick person is *necessarily* suffering from the *disease* of diphtheria simply because a positive culture has been obtained, although this is usually true. The board does insist, however, that such a person is a nucleus from which the bacilli may be spread, and remains such until the bacilli disappear. The board recognizes that the patient may be harmless, despite the positive culture, if the bacilli in his nose or throat are not actively producing toxins. But since the methods for determining that the bacilli fail to produce toxins are impossible of application in practice to large numbers of cases, the board feels justified in assuming that they are virulent on the strength of very much evidence which shows that the error involved in this assumption is small. Hence it is that a positive report on a case for diagnosis is considered sufficient evidence for the isolation of the sick person as infective.

The questions relating to virulent diphtheria bacilli in well persons are now under consideration in many quarters. An extensive investigation under the auspices of the Massachusetts Association of Boards of Health has been organized, and the results are expected to be of much interest.

None of these methods are perfect. Perfection is beyond humanity as yet. They are, however, the best at hand. Their imperfections result perhaps in occasional injustice to the individual, but on the whole the community is better protected, with less injustice to the individual, than under other circumstances. The greatest good to the greatest number must be the rule.

The meaning of a negative report. — If the bacilli are absent from a given throat or nose it is of course impossible to find them in cultures taken therefrom, but unfortunately they may be present in the throat or nose and still fail to be found in the cultures; hence, while a positive report indicates clearly the presence of diphtheria bacilli, a negative report is by no means such good evidence of their absence, particularly in laryngeal cases. This is especially true of a single negative culture but also, although to a less degree, of two or even three; thus, very occasionally, a positive result may be obtained on the fourth or fifth culture, the earlier cultures being negative.

From 5% to 10% of the cases finally proving positive fail to yield a positive result on the first examination.

The absence of the bacilli once established is complete proof of the absence of the disease of diphtheria; the difficulty is to establish their absence. Four or five negatives at least should be obtained (the more, the better) before a diagnosis of diphtheria is surrendered on bacteriological evidence alone.

The clinical diagnoses made by the physician compared with the bacteriological results of the cultures show that diphtheria bacilli are found in about 60% to 70% of the cases which the physician designates as diphtheria, and in about 10% to 11% of the cases which the physician designates as "not diphtheria." The clinical diagnoses mentioned are those appended to the card by the physician at the time of taking the culture, and of course in many cases do not represent the final clinical diagnosis which he arrives at later on, but only the tentative diagnosis at an early stage of the disease.

The meaning of a "no growth" report.— This form of report is used when for any technical reason the examination of the culture is a failure. Most of the "no growths" result from the use of dry tubes or from the growth in the serum tube of a certain bacterium or group of bacteria which liquefies the serum. The number of "no growths" has been very much reduced of late. In 1898 they formed over 2% of the total cultures; in 1899 a little less than 2%, in 1900 under 1%. In December, 1900, 3,900 cultures were examined with only 11 "no growths" — less than .3 of 1%. This decrease has been due largely to the greater care exercised by physicians in rejecting obviously dry or bad tubes, and to the increased use of the cultural test which keeps the serum tubes in circulation, affording no time for drying out. With every precaution and care, however, some cultures will be failures for the reason that the liquefying bacteria are wide spread, and occur sometimes in the throat or nose of the patient himself. In such a case the more perfect the technique of inoculation the more certain is the liquefaction of serum. In one instance, four consecutive cultures from the same patient taken on four consecutive days were all liquefied.

The meaning of a request for another culture.— If the physician states that membrane is present on pharynx and tonsils, or if the physician makes a clinical diagnosis of diphtheria, it is our custom to request another culture, should the first be negative. If what used to be called the "nose bacillus" is found in a culture for diagnosis, a request for another culture is also made, because at the present time there is considerable evidence to show that this nose bacillus may be a member of the diphtheria group and may often be virulent.

The meaning of the rapid or swab examination. — Briefly, a positive report from a swab examination has the same significance as a positive report from a culture. A negative report from a swab is absolutely meaningless. In such cases the cultural report must be waited for. In about 50% of the finally positive cases only can a positive result be obtained from the swab itself. However, since a positive swab result saves fifteen to twenty-four hours of waiting for the result of the culture, it is in this 50% of cases well worth obtaining.

Release from isolation. — The principle of release by culture in diphtheria is analogous to that of waiting for the desquamation to cease before release in scarlet fever. In scarlet fever the infective agent is supposed to be in or on the scales. These are evident to the eye, and the friends and relatives of the convalescent comparatively seldom object to the continuance of isolation until they have disappeared. The infective agent in diphtheria, however, is unfortunately only perceptible by cultural tests, and much difficulty is found at times in making clear the necessity for their disappearance before release is granted.

A scarlet fever patient grows quantitatively, though perhaps not qualitatively, less infective as the desquamation decreases. So, also, the diphtheria patient grows quantitatively, perhaps sometimes also qualitatively less infective, as the diphtheria bacilli become fewer. It is true that diphtheria is somewhat less infective than scarlet fever in the proportion of nearly 3 to 4; that is, of 100 persons exposed to scarlet fever 38 may be expected to contract the disease (Chapin),[1] while of 100 persons exposed to diphtheria only 30 will take it. On the other hand, this smaller infectiveness of diphtheria is more than counterbalanced by its greater fatality, which is, at least, double that of scarlet fever. There can be no question, then, of the expediency of isolating diphtheria patients until they become non-infective. The character of the bacteriological proof required to show that this has occurred is a different matter.

Release on one negative culture allows 30% of the total positive persons released to go out of isolation while the bacilli are still present. This is because negative cultures for release partake of the weakness of all negative cultures, in that they do not necessarily prove the absence of the diphtheria bacillus. Indeed, a negative culture for release is less reliable than a negative culture for diagnosis, because the bacilli are then fewer in number, have become scattered and, moreover, lie in the folds and follicles of the mucous membranes from which they are extruded only at intervals with the secretions. Hence, a culture may one day be negative, the next positive. Indeed, this is true sometimes of cultures taken only an hour apart.

Extensive investigation has shown that if two consecutive negative cultures for release be demanded, only 1% to 3% of those released will be still infective (McCollom). To make sure of this 1% to 3% by requiring three consecutive cultures for release would involve so much additional trouble for the physician and the patient that hitherto it has proved impracticable outside of hospitals.

NOTE. — The term "toxin" has been used in this article as an equivalent for poisons derived from a bacterial source, not in its technical sense as a particular chemical form of bacterial poison.

DESTRUCTION OF LEFT EYE AND FRONTAL LOBE OF BRAIN FROM A SHOTGUN EXPLOSION.[1]

BY EDWARD SWASEY, M.D., WORCESTER, MASS.
Oculist and Aurist to the Worcester City Hospital.

THE severe and destructive injuries of the frontal lobes of the brain form an interesting and instructive basis for physiological and psychological study. Just what functions these lobes perform in the human economy, I believe have not been fully determined. That these functions are more of the psychological than the physiological nature, I believe has been pretty well determined. We know that in man they are more developed in proportion to the remaining portions of the brain than in any other species of animals. And in different types and races of men the development of the forward part of the brain is indicative of their mental calibre and equipoise. The massive forehead we are wont to associate with the mental power of a Webster, Scott, Everett and many others, while the low, retreating forehead, the "beetle brow," we as instinctively associate with low mental power, and in extreme cases with low brutality and viciousness. But these are only broad and general conclusions, and do not tell us what the specific purpose of the so-called frontal portion of the brain is.

That the frontal lobes are of little importance in sustaining the vital functions in man has been well known for a long time. And yet I find but little explicit information regarding them in various authorities consulted. The following quotations bear on the subject as directly as any I have seen. One authority says: "Modern physiologists regard the prefrontal part of the brain as the seat of character and intellect. After removal of this part in dogs and monkeys, no paralysis of any muscles or loss of sensibility occurs, but singular changes in the behavior, emotions and character of the animals have been observed. They become livelier, restless, impatient, irritable, quarrelsome and violent. Their movements seem purposeless, and their attention to what is going on around them, and their intelligence, are diminished." "These observations," says the same authority, "have been confirmed by similar phenomena in cases of human beings." Another authority says: "Removal of one frontal lobe is comparatively insignificant in its effects, while when both are removed the change is profound. On removal of the frontal lobe in one side only, there is disturbance of vision, intelligence and character. There do occur both sensory and motor disturbances; but these, for the most part, are transient. On the side opposite to the lesion there is in the limbs a blunting of all sensation and some paresis. Moreover, there is a hyperesthesia combined with a paresis of the muscles of the neck and trunk, which move these parts away from the side of the lesion. These effects of the operation tend to pass off. If the remaining lobe be removed from a dog or monkey, not only do the symptoms first described appear on the other side of the body, but still more fundamental changes occur. A ceaseless wandering to and fro, curiosity, affections, sexual feelings, pleasures, memory and the capacity to learn are at the same time abolished; and the expressions of the animal are those of fear and excessive irritation. But that the frontal lobes are the seat of the intelligence is by no means established."

Following this brief introduction, I wish to relate the history of a case of injury to one frontal lobe which came under my observation in the City Hospital, in November, 1898. It is chiefly interesting in showing how little disturbance and reaction may follow these severe lacerations of the brain. To supplement this history by briefly reviewing some similar cases shall constitute this paper.

A boy of sixteen years of age was out gunning on a Sunday afternoon. He had an old shotgun that had contained a charge of powder for a long time. Not seeing any game, for even the birds and squirrels of quiet West Boyleston are disposed to observe Sunday, the boy's desire to make a big noise could not be resisted, and he discharged the gun, resting his face on the stock, and sighting along the barrel. There was an explosion, the boy was knocked senseless, and when picked up there was a large, ragged wound, involving the left eye, eyebrow and part of the frontal bone. He soon recovered partial consciousness, and Doctor Warren, of West Boyleston, seeing the seriousness of the injury, decided he should be sent to the Worcester City Hospital. He came in that evening, was examined by a member of the house staff, and as the boy was not suffering, having a pulse of 70 and respirations normal, he decided to let the case rest till morning.

The case was to all appearances so decidedly an eye case that I was asked to see him the next morning to do an enucleation. A large, ragged wound, involving all the supra-orbital ridge on left side, was presented. The eye was pushed downwards and outwards and nearly out of the orbit. Enucleation was done, and there it was seen why the eye was so displaced and ruptured. The superior orbital plate was pushed down, and so filled the orbit that only the tip of my finger could enter it. Large fragments of bone were found loose in the orbit and wound; and only in search of these and examining the wound in the frontal bone more carefully was the full seriousness of the case disclosed. At the outer and upper angle of the wound, hidden under the swollen tissue, I found what I supposed at first was a small fragment of iron. But on attempting to remove it I found it firmly held and quite immovable. I made several attempts to dislodge it, and only after taking strong forceps, and racking up and down and from side to side, could I dislodge this mass, after having the forceps slip off several times. Finally this breech pin and screw (Fig. 1) were removed from the wound. It was followed by quite a good deal of soft brain matter and blood, but as no large blood vessels had been injured the hemorrhage soon

[1] Read before the Worcester District Medical Society, November 8, 1899.

subsided. After cleansing the wound as best I could in this soft brain substance, the edges were brought together in an imperfect manner, because of the loss of tissue and ragged edges, and a firm compress bandage applied.

The next day he had severe headache, but pulse was 72, and he was hyperesthetic over the whole body. He then settled down to a comparatively comfortable state, with pulse respirations and temperature nearly normal.

On December 4th (operation on November 21st), or two weeks after entering the hospital, the notes say: "He can move arms and legs equally; hyperesthesia wholly disappeared; no headache, and he is comfortable."

A few days after the operation a large pulsating tumor filled and projected from the wound in the frontal bone, but was easily held in bounds by a compression bandage. He kept his bed constantly.

December 11th. The report says: "Is slowly improving; feels very comfortable."

December 14th. "Has great headache and pain in back of neck; more restless. At 8 A. M. had a convulsion that lasted some minutes. At 2 P. M. passed into a state of stupor; respirations deep. In fifteen minutes more had a second convulsion. After this he was more restless and moving about.

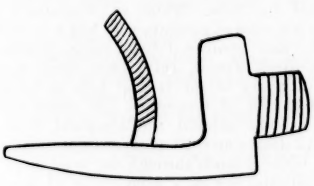

Fig. 1.

Temperature at one time was 102°, pulse from 80 to 160. Later, on same day, had a third convulsion, and more twitching of left arm and leg than of the right. Stupor continues. That evening temperature was 104°, pulse not changed."

December 15th. "No convulsions. More twitching of arm and leg; temperature and pulse unchanged."

December 16th. "All symptoms continue about the same; some movements of side of face; the left hand has a cyanotic tinge, and almost no movements in this limb. It seems paralyzed."

December 17th. "He is growing weaker; profuse perspiration on body; respirations deep and regular; temperature 104°; pulse 130."

December 18th. "Remains about the same as yesterday."

December 19th. "At 7 A. M. he died, without any material change in his symptoms."

Subsequent to the operation he was under the care of Dr. E. H. Trowbridge, for the patient entered his service on coming into the hospital.

Fortunately a post-mortem examination was secured, and was performed by Doctor Baker, pathologist to the hospital, and Dr. Adolph Meyer, neurologist to the Worcester Insane Hospital. There was found a large ragged opening, formed by the entire loss of the superior orbital plate and the supra-orbital part of the frontal bone. This opening had been filled by the pulsating brain mass. But now a large empty cavity was seen behind this opening, for the whole frontal lobe was practically destroyed by the original injury and the subsequent events. The remaining portion of the brain appeared quite healthy, except for evidences of a basilar meningitis and of the left ventricle. This lesion Doctor Meyer regarded as the sole cause of the fatal termination. The extent of the injury to the brain will be more readily understood when you see this drawing, showing the distance the breech pin entered the brain. I have taken the outline of the skull in the Medical Library, which I think corresponds closely to the size of this boy's skull. As the small end of the breech pin projected forward, the body must have taken about the position shown in the drawing. It turned through about half a circle from the gun stock to its final resting place, for the point which projects backward on the stock pointed forward in the wound. It is quite evident that part of this turning occurred after it struck the frontal bone; hence the large wound and destruction of the frontal lobe. It had entered the left ventricle, and the anterior part of the parietal lobe was wholly destroyed and disorganized. Pus was found in the left ventricle. On removing this rusty, dirty mass from the boy's brain, my first conclusion was that if he did not soon die from some meningeal hemorrhage or collapse, surely he would soon develop a severe meningitis and encephelitis that would speedily take him off. But not so, for as soon as he had recovered from shock of the operation he settled down to quite a comfortable existence for about four weeks, and then died suddenly. But why he did not develop severe meningitis rapidly, I do not yet quite understand, for I could not irrigate and cleanse the deep parts of this wound as I might almost any other tissue of the body. Possibly the soft brain substance and hemorrhage that came away removed the septic matter that was on the breech pin, for it will be remembered that this lay imbedded in the brain some eighteen hours.

The further pathological changes in this case I leave for Dr. Meyer to show and discuss. But I wish to supplement the report of this case by referring to some similar cases of severe traumatic injury to the frontal lobes, for it is only to this region of the brain that I shall refer.

The most remarkable of all these is the famous "crowbar case." In this case a bar of iron, 3½ feet long and 1¼ inches in diameter, was driven through a man's brain, entering the side of the face just in front of the angle of the jaw, and coming out at the top of the frontal bone in the median line just in front of the coronal suture. He was stunned, but after a few hours recovered himself and conversed rationally. Two days later he was delirious, and in this state, and partially comatose, he remained for three weeks, and then

began to improve. In five weeks more he could walk about. In sixteen months he was in perfect health, but the mental faculties had for a time undergone a change. He became childish, wilful, fickle and restless, and suffered loss of intellectual power. Gradually, however, these symptoms disappeared. There was permanent loss of sight on the injured side. He lived for a little more than twelve years after the injury, and for a number of years was a stage driver.

Dr. H. D. Noyes, of New York, reports a case in which the breech pin of a gun was driven deep into the right orbit and projected far up into the right frontal lobe. The mass of iron was 4½ inches long, and weighed 2½ ounces. When seen by Dr. Noyes, five months after this injury, the parts had healed over so that only by chance, in the examination of the nasal cavities, with the intention of an operation to improve the man's personal appearance, was the body found deep in the orbit and brain. The patient, a strong young farmer, had completely recovered and showed no symptoms of brain injury. Only an ugly scar and a slight discharge troubled him, and Dr. Noyes says he might have lived for many years had no attempt been made to remove this large foreign body. But it was removed, and in two weeks' time symptoms of brain abscess appeared; later,

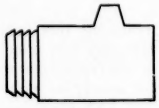

FIG. 2.

paralysis of the opposite arm and leg, and death followed, thirty-nine days after the operation.

Post mortem showed that the second and third frontal convolutions, and the orbital surface of the frontal lobe had been totally destroyed by the injury. And yet all this had given no mental sign of physical impairment in the five months this large mass of iron had remained imbedded here.

In another case a piece of iron from a shotgun was driven into a man's brain, entering the side of the face just above the centre of the zigomatic arch on the left side. The size and shape is shown in drawing (Fig. 2). In four months the man was up and about; in five months he was at work as a wood chopper in perfect health. No impairment of mental or nerve functions, only slight deafness on the same side as the injury. He then went on a spree, and while deeply intoxicated was taken over a rough road in a farm wagon for some miles. Next day he was taken with sudden and violent pain in the head and died in a few hours. The foreign body was found incysted in the anterior and inferior angle of the left middle lobe of the brain, in close proximity to the fissure of Sylvius, and the speech centre, and yet there had been no aphasia. There had been some discharge from the wound from the first. It is believed the jolting he received in this rough ride dislodged the iron from its incysted location.

In another case a rapidly revolving wheel flew into fragments, and one of these struck a young man in the left frontal bone. He was unconscious and in about ten minutes violent muscular movements began. After eight large fragments of bone had been removed he became more quiet. The longitudinal sinus and a branch of the middle meningeal artery were lacerated and the hemorrhage was quite profuse. The wound extended from the base of the nose to the top of the frontal bone, and in all nineteen fragments of bone were removed. Some hours later he became conscious, and could answer questions. He slept well that night, and the next morning the temperature was normal. On the fifth day he was sitting up in a chair. He had no pain from the first, and only for a day or two did he have a temperature of 102°. For the first three days he had diplopia, but this passed off and his sight became normal and his mind clear, so he could easily add up a column of figures correctly. Subsequently he was a bookkeeper. Gradually the space in the frontal bone was filled in by new bone, and the patient entirely recovered.

I could go on giving histories of cases on record in medical literature similar to these, but that is uncalled for here. Thus, in Wheaton's paper, giving histories of patients who had received brain injuries and recovered from same, published in the *Medical Times*, July, 1879, there were 132 cases of injury to the frontal lobe or lobes, with 58 deaths and 74 recoveries. In cases where the foreign body entered the temporal bone there were 12 deaths and 19 recoveries in a total of 31 cases, while wounds through the orbit were by far the most fatal, for in a total of 18 of these there were 17 deaths and only 1 recovery. In the parietal region there were 58 cases, 27 deaths and 31 recoveries; in the occipital region 23 cases, 16 deaths and 7 recoveries. In Erickson's "surgery" the mortality for the various regions is given thus:

The frontal region	15%
" temporal "	15%
" parietal "	13%
" occipital "	9%

This, you see, makes injuries in the frontal region quite as fatal as any, while in the occipital they are least fatal of all. Wheaton gives a total of 316 cases of foreign bodies entering the brain. Of these, 242 were musket balls or shot. In 210 cases of the total 316 cases, no attempt was made to remove the foreign body. Of these 210 cases 88 recovered and 122 died. In 106 cases of the total 316 the foreign body was removed; recovery in 72, death 34. There were twice as many recoveries as deaths when the foreign body was removed.

The reason advanced to account for the great mortality of penetrating wounds through the orbit, is that the swollen and inflamed tissues in this bony case prevent free drainage; and again gravity is against it, as the patient lies on his back. In the crow-bar case referred to the attending

physician regarded the free drainage and gravity to aid it as the chief reason for recovery. But it should be remembered that after these cases have recovered, and very likely appear to be quite themselves for a time, later on some impairment of mind or body appears — incapacity for physical exertion, vertigo, epilepsy in some of its forms, paralysis, and possibly insanity. For example, one case on record: The musket ball entered just behind the outer angle of the left orbit, destroying the sight of the eye and lodging behind it. This was an insignificant injury compared with many others in this list, but strange to say, it was followed by almost complete loss of memory, which was permanent.

I had an almost identical case in the City Hospital a few years ago, in which a small pistol ball entered just back of the outer angle of right eye. It destroyed the sight in this eye, rupturing the choroid and retina, and injuring the optic nerve. I tried to find and remove the ball by going in behind the globe, but failed to find it. It is there today perfectly quiescent, and has left no mental impairment and no deformity. It is not safe to early predict what these injuries will leave in their wake, for trifling ones may be followed by strange results, while serious ones may leave but comparatively little change, either mental or physical.

In the discussion which followed this paper, Dr. E. R. Wheeler, of Spencer, Mass., presented a patient with a history that tallies very closely with those here referred to. This was the history of the case as Dr. Wheeler has kindly given it to me:

On January 28, 1899, a man, forty-four years of age, was sawing wood with a rapidly revolving circular saw. It broke into fragments, and one of these struck him in the forehead. It cut through the visor of his cap, through the frontal bone and orbit of the right eye, near the inner angle. This fragment of bone was pushed upwards and outwards so it stood fully ¼ inch higher than the remaining part of the skull. This elevation was permanent. A finger could be introduced between the edges of the bones from the orbit to the centre of the forehead. The fracture extended on to the vertex, and from here to the top of the ear, which perhaps followed the coronal suture. A small piece of the orbit was removed, and about a teaspoonful of brain substance came away.

At the time of the injury and for a few days following there were hallucinations on some subjects, but these symptoms soon passed off. He made an uninterrupted recovery, and in about three months resumed his work, apparently as well as ever.

In August 1899, about seven months after this injury, he had an epileptic attack; and at intervals of about once or twice a month these recurred. They became more frequent, until August 16, 1900, when he was found dead in bed, having probably had an attack in the night in which he died.

CONVULSIONS IN CHILDREN.[1]

BY WILLIAM N. BULLARD, M.D., AND CHARLES W. TOWNSEND, M.D., BOSTON.

THE occurrence of a convulsion in a child is always a startling event; but it is often believed to be of little import, and due to some reflex irritation acting in the sensitive nervous organization of the child.

Of the recognized causes of convulsions in children, such as gastric irritation from improper food, the presence of worms, irritation of the ear, the onset of acute disease, all are of more or less frequent occurrence, and yet the majority of children do not respond by convulsive seizures to these irritations. It would seem, therefore, of interest to study the general condition, and after career, of those children in whom convulsions have occurred.

A certain proportion of cases of convulsions in early childhood are but the beginning of true epilepsy; and it may for a time be impossible to say in a given case whether the convulsions are reflex and temporary, or whether they will eventuate in permanent epilepsy.

We have examined all the out-patient records of the Boston Children's Hospital from the start, in 1883, to December 31, 1894, and, out of 7,180 cases in all, we have found 79 cases entered as eclampsia. Of these, 6 were manifestly cases of epilepsy with or without idiocy, leaving 73 cases of eclampsia, or 1% of the entire number of children. During these eleven years there were 51 cases recorded as epilepsy.

An examination of these records showed that 10 of these should be placed in the doubtful list, some being merely reflex and temporary, while of the 41 true epileptics 12 were also idiots. This does not include the epileptics who came to the special clinic for nervous diseases. Of these 73 cases of eclampsia, 24 have been seen or heard from lately. Six cases from private practice have been added, making 30 in all. It was thought best to investigate only those that had been seen for the first time at least five years ago. Some of them were seen as long ago as sixteen years. Of the 30 cases, 4 are dead. One of them continued to have frequent convulsions from the age of five years to his death, at ten, from pneumonia. Another continued to have convulsions from the age of two till five, when they ceased, and a year later he died of croup. A third, a child of five, who had had a few convulsions, believed to be due to worms, died six months later of tubercular meningitis. A fourth died three months after being seen at the hospital, of hemoptysis. Five more cases proved to be feeble-minded or epileptic, although the diagnosis was not made when first seen at the hospital. One of these children, seen first when seven years old, after a fit, thought to be brought on by eating sausage, continued to have fits till the age of thirteen. He is now seventeen years old, in poor general condition, and of poor mental calibre. Another patient was seen

[1] Read before the Clinical Section of the Suffolk District Medical Society, January 16, 1901.

at the hospital when ten years old, for occasional convulsions occurring without apparent cause during the preceding two months. These continued for a year, and were succeeded by slight attacks of petit mal. The boy, now fifteen years of age, appears bright and well, and is an elevator boy! The risk to himself and his passengers is evidently not understood.

Subtracting these 10 cases, we have 20 left that are living today and free from convulsive attacks; seventeen of these are bright and well, although one wets his bed, at ten years of age, every night, and another has had chorea. Three are very nervous, one being neurasthenic and despondent. All of the private cases are well and bright.

A study of the supposed reflex causes of the convulsions in these cases of temporary eclampsia may be interesting. In 6 the convulsions were traced to improper food, 5 of these at once ceasing to have convulsions when the diet was regulated. In 2 cases the exciting cause seemed to be a fright; in 1 a fall; in the other from being run over. In two, round worms were supposed to be the cause of the trouble; in one constipation. Two were cases of eclampsia occurring soon after instrumental labors. A few of these cases are worthy of special mention.

CASE I. A girl, seen at the age of four for two convulsions supposed to be due to worms. She is now twenty years of age and in excellent health, but her convulsions occurred every two or three months till she was sixteen years old, or *two years after* the *appearance* of the *catamenia*, when they ceased and have never recurred.

CASE II. A girl was brought to the hospital when two years old for convulsions, which began five weeks before. She is now thirteen years old, well and bright; the convulsions lasted for a year longer and were very numerous, sometimes as many as fifty in a day. When three years old she had measles, and has never had a convulsion since.

Of the 6 cases from private practise, 2 are cases of convulsions occurring during the first few days of life, following difficult labor in primiparæ, with forceps extraction. One of these had several convulsions during the first twenty-four hours; recovered, and is a healthy boy of ten years today, never having had any more convulsions or any nervous diseases. The second, a girl, had convulsions at intervals of every hour for three days. She is now a healthy child of eight years, free from any nervous or cerebral trouble. A third case, seen in consultation with Dr. W. E. Boardman, had convulsions after a normal labor, from the end of the first week for two succeeding weeks, so numerous that seventy were counted in one day. They ceased abruptly after purgation by calomel, and the child, now three years old, is well and strong.

The three other cases are examples of reflex convulsions appearing in apparently healthy children, and not followed by any untoward consequences.

CASE I. A boy, age fifteen months, had eaten a piece of mince pie. Four hours later the child went into a convulsion which lasted almost continuously for two hours. Two slight convulsions followed seven hours and nineteen hours later. The child, eleven years old today, has been free from convulsions since, and is well.

CASE II. A girl, three years and four months old in 1894, was discovered eating sugar out of a bowl with both hands. She vomited, was feverish, had a convulsion followed by a large, foul dejection. She has not had any convulsions since.

CASE III. A boy, twenty months old in 1895, had a convulsion lasting from one-half to three-quarters of an hour. His diet was simple, chiefly milk, oatmeal and bread, and there was very little chance of improper food having been given him. He was cutting his canines at the time. He is bright and well today and has not had any more convulsions.

To approach the subject in another way, and ascertain the relative frequency of temporary eclampsia in children, the parents of those from five to twelve years old were questioned at the Children's and Massachusetts General Hospitals as to the occurrence or non-occurrence of fits in these children, and the children were examined. Of 195 children examined in this way, 19, or 10%, had had one or more convulsions. Of these 19 children, 7 are strong and well, 9 are decidedly nervous, and 3 were considered not nervous but delicate. Three of these were troubled with eneuresis, 2 with insomnia, and 1 with night terrors; none had had chorea. The supposed causes of convulsions in these cases were as follows: Onset of acute disease 4, in 1 case scarlet fever, in another empyæma, and in 2 others measles; worms 1, teething 2, constipation 2, improper diet 3.

Our results may be summed up as follows: (1) One per cent. of the children applying for treatment at the Children's Hospital came for convulsions; (2) 10% of children between five and twelve years of age gave a history of convulsions; (3) cases that appear to be due to some manifest reflex cause may turn out to be true epilepsy; (4) other cases, where the attacks occur frequently and without apparent cause, may suddenly recover, at least, for a considerable period; (5) children who have had convulsions may be strong and free from nervous tendencies in later life, although the proportion who have nervous tendencies seems to be greater than in those who have not had convulsions.

THE SMALLPOX SITUATION IN CHICAGO. — It is reported according to the *Medical News* that only 17 new cases of smallpox have occurred during the past week. At the close of the previous week there were 44 cases in the isolation hospital; 17 were admitted during the week, and 23 discharged, with no death, 38 remaining under treatment. With one exception the cases are mild. It is announced that the stock of glycerinated vaccinelymph on hand has ripened sufficiently to make the resumption of vaccination safe.

Clinical Department.

ACUTE PANCREATITIS.[1]

BY M. H. RICHARDSON, M.D., BOSTON.

THE subject of Dr. Lund's paper is one of great interest to me, and it has been presented in a most interesting manner. One can say nothing in the way of adverse criticism. Dr. Lund has had the fortunate experience of seeing one or two of these cases of acute pancreatitis recover. In all the cases that I have seen in which this diagnosis was confirmed death has followed. It seems as if the time had come when we ought not to content ourselves with leaving these cases to themselves. The occasional occurrence of disseminated areas of cicatrization in the peritoneum — the yellowish spots referred to by Dr. Lund, and which I think every abdominal surgeon not infrequently sees — seems to show that recovery follows mild cases of fat necrosis. The severe cases are essentially fatal, and are among the most terrible of abdominal emergencies. It is to be hoped that by earlier recognition, and by earlier and more thorough methods, we may reduce the almost prohibitory mortality of operations thus far performed.

I have seen a number of cases of suppuration in the epigastrium, in the lesser cavity of the omentum. My first case was one which Dr. Elliot thought had probably started from a suppurating pancreas. There was no reason to think it was the pancreas except that the woman had a large abscess in that region. She was a "fat old woman who may have had gall stones." We simply drained the abscess, and she made a good recovery. I have drained abscesses in the epigastrium in four or more instances, but I have attributed them to other causes than pancreatitis. One occurred in a girl who had been in the habit of swallowing rubber gum. I supposed that the gum had collected in the stomach and that a perigastritis had resulted. This was indeed the fact. In another case in which I operated for Dr. Dudley, of Abington, we found extensive retroperitoneal hemorrhage. The man died, and an autopsy was not obtained. I have operated in another instance for what I supposed was suppuration of the mesenteric lymph glands situated near the pancreas. The patient, a girl, recovered, but died later of pulmonary tuberculosis. I have used this case as an illustration of possible mesenteric tuberculosis and suppuration. One case was undoubtedly an acute hemorrhagic and suppurative pancreatitis. My patient was a girl of nineteen, who was apparently moribund. I thought at first that there would be no use in operating, but finally decided to open under cocaine the epigastrium where the guiding symptoms lay. We gave her chloroform finally. The wound gave exit to enormous quantities of bloody serum, and to masses supposed to be pancreatic fat. To my surprise, the girl recovered from the operation and did well four weeks, toward the end of which time she began to cast off large masses of sloughing pancreatic tissue. She was doing fairly well, when suddenly she died. An autopsy was not obtained. On the same day a similar case was operated upon at the Massachusetts General Hospital. The patient, a man, also died at the end of about four weeks, after doing well.

I have listened to the paper with great attention and interest, and I think that the conclusions are warranted. In all obscure inflammations of the epigastrium, attended by acute sudden pain, we ought to explore. If we cannot do anything else we can at least drain. From the nature of things I do not suppose that we can save many cases. The frequency with which the diagnosis of pancreatitis has been made is suggestive. In all obscure cases of sharp pain high up in the abdomen the one who always says "acute pancreatitis" will sooner or later be right. I have said it many times, but never was right. The fact is, that the diagnosis of these obscure lesions is practically impossible unless time is taken for study, which the imperative call for operation forbids. The only case of mine in which this lesion was really found was one in which it had not been suspected. The last case in which this diagnosis was made was only two weeks ago. One of my assistants thought the lesion an acute pancreatitis; a consultant, intestinal obstruction; the rest of us made no diagnosis. Under ether it was plainly an acute appendicitis — in other words, it proved to be what almost all obscure acute inflammations in the abdomen prove to be — an acute appendicitis with general peritonitis.

CASE OF RECOVERY AFTER OPERATION FOR ACUTE PANCREATITIS.[1]

BY J. C. MUNRO, M.D., BOSTON.

The patient was under the care of Dr. Flanders, of Jamaica Plain, and was seen also by Dr. Jackson. When I saw her there was general abdominal pain, tenderness and spasm in both hypochrondria and in the epigastrium, with a tumor in the latter region, extending into the left lumbar region. The diagnosis was some retroperitoneal infection. At that time Dr. Flanders thought of pancreatitis, but personally I did not give it much credence. There was a history of recurrent attacks of gall stone, and I thought it more likely that a large gall stone had perforated the posterior peritoneum and produced a retroperitoneal lymphangitis, extending across to the kidney. On the following day, March 8th, I operated, and found the omentum full of fat necrosis, and behind that a large tumor which increased in size towards the left. I introduced the fingers into the tumor and found that there was no pus, but that it broke up rather easily. With one finger

[1] Contribution to the discussion of a paper on "Acute Hemorrhagic Pancreatitis," read by Dr. F. B. Lund before the Boston Society for Medical Improvement, Nov. 26, 1900. See Journal, November 29, 1900.

as a guide I opened on the left side and thoroughly broke up the pancreas as much as I could, and then closed the first wound and drained through the second. The operation was not well borne; in fact, I thought she would die on the table. For some days she was very ill, and then discharged an enormous quantity of material resembling pea soup, with a sweet odor. She went along well for about a month, when suddenly the temperature rose to 104° or 105° F., and she again became very ill. I explored the sinus and opened into another large cavity which contained a similar material. She recovered from that, discharging a good deal of this material, but still she had not pulled up as much as she ought, and four days later I opened through the sinus into another cavity that went up behind the lesser peritoneal cavity. At the lowermost part of all these cavities a free opening was made in the loin. She continued to discharge the greyish material, for some time, but finally the sinus closed and she has been well ever since, except for one or two slight gall stone attacks. She has gained in weight, and apparently digests everything.

She was very, very ill, but to the good nursing and to the excellent care of Dr. Flanders I think she really owes her recovery. I drained with a glass tube and iodoform wicks, removing them in forty-eight hours, when there was this gush of material resembling pea soup.

Medical Progress.

RECENT PROGRESS IN THORACIC DISEASES.

BY GEORGE G. SEARS, M.D., AND JOHN W. BARTOL, M.D., BOSTON.

THE POSITION OF ACUTE PERICARDIAL EFFUSIONS.[1]

As a result of experiments on the cadaver, Aporti and Figaroli[1] reach the following conclusions:

(1) Pericardial effusions can be demonstrated by percussion only when they exceed 150 or 200 cubic centimetres.

(2) Six hundred and fifty to 700 cubic centimetres is the maximum which the pericardium can contain. (This must refer to the maximum amount which can be injected after death, since clinical experience has shown that it may contain much larger amounts.)

(3) With the patient on his back, the cardiac dullness extends in all directions proportionally to the amount of exudate, while in the vertical position the dullness is more marked in the region of the apex beat and the cardiohepatic angle. In the first instance the anterior surface of the heart is only partially, in the second it may finally become fully covered.

(4) In the horizontal posture the great vessels are surrounded by the exudate when present only in small amount, while in the erect position the base of the heart remains free even in the presence of a large quantity of fluid.

[1] Centrl. f. inn. Med., July 21, 1900.

CARDIOPTOSIS.

Ferrannini[2] speaks of displacements of the heart which are secondary to changes in other organs, and then discusses the primary essential ptosis of the heart, which was first described by Rummo.

He refers to the various theories which have been formulated to account for enteroptosis in general and cardioptosis in particular, and reports 4 new cases of primary cardiac displacement. They occurred in adults between eighteen and thirty-four years of age, 2 men and 2 women, in none of whom was there any hereditary taint. Ali showed a marked epigastric pulsation. On percussion, the lower border of the heart extended $3\frac{1}{2}$ to $4\frac{1}{2}$ centimetres below the ensiform process, while above the relative dullness began as low as the third rib, the third interspace or even the lower border of the fourth rib. There could, therefore, be no doubt that he was dealing with a displacement of the organ and not an enlargement. Auscultation showed the presence of mitral stenosis in all cases. In all four patients certain abnormalities of development were found as shown by the disproportion between the face and the rest of the skull, the slender bones, the small stature, and the deformities of the thorax and extremities. In one there were pronounced mental defects.

[2] Centrl. f. inn. Med., November 1, 1900.

"HILL HEART."

Campbell[3] describes rather picturesquely the form of heart disease which he finds especially common in hilly districts. This is a degeneration of the muscle (with preceding hypertrophy) which, although not serious enough to prevent attendance on usual pursuits or produce symptoms of back pressure, offers a constant menace to the individual, because any extra strain may result in alarming and dangerous attacks; thus may arise marked distress (anginal), dyspnea, syncope or even apoplectiform seizures, which not infrequently terminate in death. There is a report of cases which sufficiently support his description, and in closing, an explanation that the condition differs from the ordinary fatty degeneration in the existence of an antecedent hypertrophy and a consequent greater liability to the epileptiform or apoplectiform attacks, which are associated with a temporary increase in the blood pressure, a forcible action of the heart indicated by excited tumultuous movements and anginal pain, these effects being increased by the upward pressure of a dilated stomach, which is very apt to be an accompaniment of the conditions.

DIASTOLIC EXPANSION MOVEMENT OF THE VENTRICLES A FACTOR IN COMPENSATION OF MITRAL DISEASES.

In a paper largely theoretical, and based chiefly on evidence of the cardiogram, Wilson[4] attempts

[4] British Medical Journal, September 29, 1900.

to prove that the heart has the power to enlarge its chambers by a true muscular expansion movement. The figures accompanying the paper are necessary for a clear understanding of the points in question.

ACTION OF THE HEART IN MITRAL STENOSIS.

Gibbes[5] reopens the question of the origin of the presystolic murmur. He is opposed to the Ormand-Barclay theory, that it is a regurgitant murmur; and while holding with Gairdner that it occurs before contraction of the ventricle, he considers that it is composed of three different parts. (1) Audible right ventricular muscle vibrations. In consequence of the two ventricles not acting synchronously, a portion of the right ventricular systole takes place, and its muscle vibrations are heard, while the left ventricle is in diastole; (2) a murmur caused by the flow of blood from the left auricle into the left ventricle; (3) the slapping first sound; this is part and parcel of the murmur, and ought to be so considered."

His objections to Gairdner's conclusions are based on the recognized unreliability of cardiograms, a point which seems well taken, but his own explanation is also insufficiently supported by a single clinical case and theoretical reasoning based thereon. Further discussion of the same and allied points may be found in a suggestive paper by Ewart[6] on Mechanism of the Heart and its Valves. *(To be continued.)*

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

HENRY F. HEWES, M. D., SECRETARY.

REGULAR meeting Wednesday, January 16, 1901, DR. ARTHUR K. STONE in the chair.

DR. FRANKLIN W. WHITE and DR. MAYNARD LADD read a paper on

WHEY CREAM MODIFICATIONS IN INFANT FEEDING,

of which the following are the conclusions:

(1) By the use of whey as a diluent of cream of various strengths, we are able to modify cow's milk so that its proportions of caseinogen and whey proteids will closely correspond to the proportions present in human milk. We thereby rendered it much more digestible and suitable for infant feeding.

(2) The best temperature for destroying the rennet enzyme in whey is 65.1°C. Whey or whey mixtures should not be heated above 69°C., in order to avoid the coagulation of the whey proteids. The percentage of whey proteids in the whey obtained by us was 1%; while in the analysis of the whole milk approximately three-fourths of the total proteid was caseinogen and one-fourth was whey proteids.

(3) On the basis of the analysis we were able to obtain whey cream mixtures with a maximum of .90%, and a minimum of .25% of whey proteids in combination with percentages of caseinogen, varying from .25% to 1%; of the fats, from 1% to 4%; of milk sugar from 4% to 7%.

(4) The emulsion of fat in whey, barley water, gravity cream and centrifugal cream mixtures were the same, both in their macroscopic and microscopic appearances. The combination of heat and transportation, such as sometimes occurs in hot weather, partially destroys the emulsion in all forms of modified milk, but this disturbance can be prevented by the simple precaution of keeping the milk cool during delivery.

(5) Whey cream mixtures yield a much finer, less bulky and more digestible coagulum than plain modified mixtures with the same total proteids; the coagulum is equalled in fineness only by that of barley water mixtures. The coagulum yielded by gravity cream and centrifugal cream mixtures is the same in character.

DR. T. M. ROTCH: These experiments, on which Doctors White and Ladd have spent months, are very valuable to us who are engaged in infant feeding, and a great deal of credit is due to both of them. The chief points upon which they have thrown light are: (1) In regard to the globule of fat which appears on the top of the milk in certain cases. I think they have clearly shown from what it comes and how it can be obviated. It is also very satisfactory to know that this can be obviated apparently without militating against what we are trying to accomplish in modifying the milk, whether at home or by laboratory modification. (2) The clearing up of what has been said about barley water. Some of us supposed that barley water did not break up the curd, but I think the writers prove that it does. They have gone further. They have performed a series of experiments showing us how we can accomplish what we believe to be the rational feeding of infants, namely, by a nearer approach to human milk in regard to the proteids, making the amount more closely approximate that contained in human milk.

As soon as Doctor Westcott suggested to me that the total proteids in our modifications of cow's milk was very different from that of human milk, and that the amount might be made to approximate closely by using whey albumin and the proper proportions of caseinogen, I adopted this method clinically, and began to have infants so fed to see whether we could accomplish good results. I think it is yet too soon to say whether we are to have any especially brilliant results, but it seems to me it is a step in the right direction. I suppose what we all try to accomplish, when we cannot give human milk, is to copy human milk as closely as possible, and we meet with especial difficulties when we attempt to deal with the proteids. The total proteids in cow's

[5] Edinburgh Medical Journal.
[6] British Medical Journal, October 20, 1900.

milk differ from the total proteids in human milk, and, therefore, have to be modified. It has been shown in the paper that in using whey for the purpose of modifying the proteids it is possible to get almost 2% total proteids, and yet have two-thirds of that correspond to the whey albumin and one-third to caseinogen, which is the relative proportion of these elements in human milk. This is valuable in that you can still get such a high total proteid. Two per cent. of total proteids is something which we aim at getting, perhaps at the fourth or fifth month, but in many cases not until the sixth or seventh month. My idea is that we should aim not only to copy the human proteids but also to accustom the infant to take the total proteids of cow's milk by the end of the first year. This should be done very gradually. The low proteid per cent. obtained by using whey is well adapted to the young infant, and as the infant grows older and the higher total proteid per cents are indicated and the higher relative per cents of the whey albumen cannot be obtained, the infant has arrived at an age when it will be able to take a higher relative percentage of caseinogen of the cow's proteids.

In this way, by the end of the first year it has not only been accustomed to take the total proteids of cow's milk, but also to take that proportion of caseinogen — three-fourths caseinogen to one-fourth whey albumin, which is in the cow's proteids.

In regard to the clinical results: We must have a great many more cases before we can give a definite opinion. I have been using the whey for modification in quite a number of cases, and am so far well pleased with the results. Just as it often happens, when I am using a home modification, I find that I cannot get the percentages modified exactly and minutely enough, I have to give a laboratory modification until the infant can take a home modification; so I find the total proteids of cow's milk without this further subdivision with whey give me difficulties which can be obviated by giving the proper proportions of whey albumin.

This is a great step in advance in our system of modification for infant feeding. It is working on the right basis. This paper is an exceedingly valuable one, and the best that has appeared for years on the subject of infant feeding and modification.

DR. C. W. TOWNSEND: I congratulate Drs. White and Ladd on their careful work. It is very interesting to me. Two points they brought out especially are really old points. One is the use of whey and the other the use of barley water. Both of these were very strongly recommended in the textbooks fifteen or twenty years ago. Whey I have never used myself, but I have very often used barley water and oatmeal water, and always believed that clinically it did make a difference with the digestibility of the curd, and I am very glad to have this so thoroughly confirmed by these experiments.

The use of whey, though theoretically a good thing, calls for a good deal more manipulation of the milk, and I cannot help feeling that the less manipulation we make of the constituents of milk, the better it is for the infant. Though, theoretically, it may be better to split up the albuminoids of the milk in this way and combine them again, still I believe that the less manipulation that is made the better. I have used a great deal the white of egg, which I believe corresponds very closely to lactalbumin, and which can be very easily added in home modifications. I very often use it where I have to begin with the weak albuminoids of twenty or forty or sixty hundredths of 1%, adding the white of one or two eggs to the mixture of twenty ounces, and in that way am able to increase the amount of albuminoid very much, and increase the nutritious quality of the milk without throwing too much stress on the digestive organs. Of course that is a familiar way, and it seems to me a practical way for home modifications until a simple way is found for using whey, and it seems to me it is a question then, whether it will be desirable to manipulate the milk to the extent necessary to get the whey — whey of a character we can be sure of, and which can be used in the modification of milk for infants.

DR. A. H. WENTWORTH: I wish to call attention to the fact that this method of preparing infants' food by the use of whey is not a new one. It was described by Professor Backhaus of Göttingen in 1896. The article appeared in two numbers of the *Allgemeine Med. Central Zeitung* in September, 1896. The method was found to be a practical one, and has been used in various European cities ever since. Favorable reports of results obtained by its use have been published. Biedest speaks well of it in his book published in 1897. Kolisko published an article in the *Archiv für Kinderheilkunde*, 1899, in which he gave the clinical histories of a number of infants fed in this way. The infants were much emaciated and his results were surprisingly good. It is only fair that the credit should be given to Backhaus and not to Westcott. Backhaus's work was carefully performed and controlled. Analysis of the various mixtures always gave the same results.

As to my own experience with this method of feeding, I have but little to say — I have used it in the hospital in a number of cases and once or twice in private practice.

In the hospital cases the results appeared to be about the same as when weak modifications of milk were used, so far as the dejections were concerned. It must be stated that the cases that were fed in this way had had digestive disturbances for weeks or months; they were in bad general condition and much emaciated. Such cases do not do well in hospitals after two or three weeks in any treatment. As a rule all that is accomplished in hospitals in such cases is to relieve acute symptoms and to find a food that is more suitable than the old one. Not much improvement can be expected after two or three

weeks unless they obtain fresh air. I should not draw any conclusions from my experience thus far.

The good results obtained abroad in the *same class of cases* probably depends largely on the fact that they were out patients, and were not confined in a hospital. Many of Kolisko's cases were under observation for several months.

Dr. E. M. Buckingham: I have only two things to say. One is to compliment the writers upon a valuable paper. The other is that, clinically, I have long been of the opinion that there is a tendency to reduce the albuminoids too much. Of course the reason for this is clear. Here is possibly a way in which such over-reduction may be sometimes avoided.

Dr. Maynard Ladd: There seems to be a slight misunderstanding in regard to the question of priority. We make no claims that this is a new method and take no credit upon ourselves for it. It is simply a development of the principle of using whey in order to raise the percentage of soluble proteids without increasing the caseinogen, and without altering the character of the proteids. Westcott, I think, was the first to call the attention of physicians in this country to the theoretical objections to the present method of dealing with the proteids by the simple reduction in the amount of total proteids, and he did this rather recently. I was not aware of the work done by Backhaus, but should judge from what Dr. Wentworth has said of it that it differed in many respects from our own. The chief point in our experimental work was to develop the system in order that physicians might be able to write for definite percentages of caseinogen and whey proteids, in combination with varying proportions of fats and sugars, at the milk laboratories. This has not previously been possible, and now can be done. We can write for percentages of fats, sugars, caseinogen and whey proteids in the proportions indicated on the board. This is not new, but only a development, just as the work of Backhaus was a development of the work of Monti and many others who preceded him in the use of whey. I am sure that there is no disposition to claim any priority over any one else's work, but simply to make the use of whey cream modifications practicable for use here in Boston and in other cities.

Dr. F. W. White: It is perfectly true that the method is not a new one, and that work on this subject has been done on the other side of the water. Monti has spoken many times of the value of mixtures of whey and cream in infant feeding. Our experiments were made in order to improve the method of making whey cream mixtures, and to render it more accurate if possible. We wished to apply it to American milk, and make it practicable in the milk laboratories.

Dr. Wentworth: My remarks did not refer to the work of Drs. White and Ladd: I wished to make it clear that the credit of devising the method of feeding belongs to Backhaus, and not to Westcott.

In answer to a question by Dr. Rotch, Dr. Wentworth said that Backhaus had done the same work as Westcott. Had worked it out mathematically and tested it. He did not use so many combinations, because he believed that three or four would do — a weak one; stronger one, etc. The work was performed accurately, and control analysis yielded the same results as to the percentage of whey proteid, casein, sugar of milk, fat and solids. It was not simply a "whey mixture" with milk. A high fat was obtained by centrifugalizing the milk. The whey proteids were obtained from the milk by the action of rennet in the presence of teyhsin and bicarbonate of soda. Definite quantities of cream, milk sugar, whey and water were mixed together. The following mixtures are supplied to the public by a Vienna firm, namely:

	I	II	III
Fat, per cent	3.1	3.2	3.3
Milk sugar, per cent	6.0	5.4	4.8
Casein, per cent	.6	1.8	3.0
Albumin, per cent	1.0	.3	.5
Salts	.4	.4	.7

Drs. W. N. Bullard and C. W. Townsend read a paper entitled

CONVULSIONS IN CHILDREN.[1]

Dr. Rotch: There is no question that in early life there is such a strong tendency to reflex nervous explosions that we have a very large number of these cases represented by convulsions. I have seen infants who have had forty to fifty convulsions in the twenty-four hours; proved to be dependent on an unusually high proteid in the mother's milk, the proteid per cent. running up to 3%, or even to the percentage of proteids in cow's milk. These are interesting cases, and get entirely well when the high proteid percentage is reduced, so that we should always be very guarded in making a diagnosis of epilepsy in such cases. A large number of cases diagnosticated as epilepsy are eventually proved not to be epilepsy at all.

Recent Literature.

Bruce's Principles of Treatment. The Principles of Treatment and Their Application to the Practice of Medicine. By J. Mitchell Bruce, M.D., F. R. C. P., Lecturer on the Practice of Medicine in Charing-Cross Hospital, London; Examiner in Medicine, Royal College of Physicians, London. Revised to conform with the U. S. Pharmacopeia. By E. Q. Thornton, M.D., Jefferson Medical College, Philadelphia. In one octavo volume of 625 pp. New York and Philadelphia: Lea Brothers & Co. 1900.

This book takes the place to the busy doctor of a friendly talk with an older or more experienced physician. It does not contain original ideas, nor are all its therapeutic hints up to the modern

[1] See page 233 of the Journal.

standard, but it does offer a wealth of suggestions which are conservative and practical.

The first part of the book (267 pages) deals with the Principles of Treatment, while the remaining portion is devoted to the illustration of these principles in chapters on the treatment of the more important diseases. The general plan of procedure is illustrated in the chapter on pneumonia. First comes a resumé of the disease from the therapeutic standpoint. This is followed by short sections on the Etiological Indications, Pathological Indications, Clinical Indications comprising the chief part of the chapter, and, finally, Indications from the Course. Then come two to three pages on the Outline of Practice. This portion is divided into the commencement and progress of the case, with various sub-topics, such as At First Visit, General Management and Nursing Diet, Local Measure, Medicines; At the Second Visit, At the Crisis, In the Post-critical Stage, In Convalescence.

The book is pleasantly written, but the first part is rather long drawn out.

The Treatment of Pelvic Inflammation Through the Vagina. By WILLIAM R. PRYOR, M.D., Professor of Gynecology, New York Polyclinic; Consulting Surgeon, City (Charity) Hospital; Visiting Surgeon, St. Elizabeth Hospital, New York City. With 110 illustrations. Philadelphia: W. B. Saunders. 1899.

This book is the result of the author's desire to popularize the vaginal methods of dealing with acute pelvic inflammation. He is inclined to believe that these operations are within the powers of the general practitioner, and that the attempt to refer them to specialists leads to unnecessary delay. Whether one agrees with him in this, or believes on the other hand that an inefficient performance of a specially difficult operation would be worse than the delay involved in sending for a qualified operator, one must at least grant that Dr. Pryor's book is admirably calculated to do all that any printed work can do to teach the general practitioner vaginal surgery.

The first half of the book is devoted to a lucid and thoroughly up-to-date statement of the pathology of pelvic infection, treated from the bacteriological as well as anatomical standpoint. The remainder is made up of an exposition of the methods of operating carried out in the most minute detail.

LEPROSY IN CANADA.—The extent of leprosy in Canada, as stated in the *Philadelphia Medical Journal*, is shown in the last annual report of the Minister of Agriculture. In this appears a subreport from the medical superintendent of the Lazaretto at Tracadie, N. B., Dr. A. C. Smith, for the twelve months ending the 31st of October, 1900. There are 20 inmates at the Lazaretto, 13 males and 7 females. Their ages range from nineteen to sixty-four years; and 7 of the inmates may be classified as being in the first stage, 12 in the second, and 1 in the final stage of the malady.

A HOSPITAL FOR TUBERCULOSIS IN BOSTON.

THE urgent need of a hospital under the jurisdiction of the city, for persons suffering from tuberculosis has increased with the growth of the population and the crowding which is its inevitable result. The State has made partial provision, at least, for the consumptive poor, but the centres of population are still without proper means of caring for this increasingly large number of dependents. It is eminently natural and proper, therefore, that public spirited persons should take up the question, bring it before the appointed authorities, and inaugurate such reforms as the situation demands. The need is apparent; the best method of meeting it demands careful and far-reaching consideration.

It is no doubt generally known to our readers in this vicinity that a petition to the city government has been drawn up, and signed by a large number of prominent physicians and others, requesting that measures be taken for the establishment within the city limits of a suitable hospital for the care of persons ill with tuberculosis. The wording of the petition is as follows:

TO THE HONORABLE, THE MAYOR AND THE CITY COUNCIL OF THE CITY OF BOSTON:

The undersigned citizens and taxpayers of this city respectfully represent that the Board of Health herein established has by a regulation issued May 1, 1900, included consumption, called in said regulation pulmonary and laryngeal tuberculosis, in the list of diseases requiring compulsory notification, and after the removal or death of the patient disinfection of the premises.

That such cases of consumption constantly and frequently occur in families of the poor living within the city limits in places where the danger of contagion or infection is always great, while no means of providing for their special care and treatment here exists, although the proper protection of the public health so requires.

Wherefore your petitioners pray that by establishing a hospital and appropriating money therefor, or by

such other method as upon due consideration may seem best, the city provide for the special care and treatment of consumptive patients who, by reason of their condition in life, are unable to procure the same.

Signed: Frederick I. Knight, M. D.,
Edward O. Otis, M. D.,
B. S. Ladd,
Mary Morton Kehew,
Agnes Vietor, M. D.,
A. K. Stone, M. D.

It has furthermore been recommended, but from what source we do not know, that the Marcella Street Home, in the Roxbury District, be transferred to the Board of Health, to be used for such a hospital. This proposition has already met with a certain amount of objection from one branch of the city government, and also from the residents of the neighborhood in question. How strong these objections may prove to be, we have no present means of knowing. If sufficiently strong pressure be brought to bear they may, no doubt, be overruled; in the meantime, however, it is desirable to consider both the disadvantages and the advantages of this site for such a hospital, and also to see if there is any other feasible alternative for the care of the city's consumptive poor.

The disadvantages of the Marcella Street Home are sufficiently apparent. It is an old building; it is not provided with extensive grounds; it is situated in a considerably settled neighborhood, the population of which is likely to increase. The recognized attributes of a hospital for tuberculosis, uncontaminated air and space, are not likely to be attained by the conversion of this building into a hospital. Furthermore it must be borne in mind that the opening of such an institution immediately necessitates its proper maintenance. This means the appointment of a superintendent, resident medical officers, and a nursing staff, not to speak of the many incidentals which the conduct of an independent institution demands. All this should be considered before final steps are taken in so important a movement as this appears to be. We do not question that the signers of the petition to which we have alluded had these objections more or less in mind; their general attitude no doubt was, that it is desirable to take some decided step in the matter, even if the conditions are far removed from what they might wish. In lieu of a better building and site, it is well, for the present, to take advantage of what we have, and start the hospital for tuberculosis at the Marcella Street Home. With this line of argument we have no quarrel; it is the one which in the face of existing political conditions must be used. There is, nevertheless, one other alternative, which has apparently not received the serious consideration it deserves, and that is, the possibility of the establishment of such a hospital on Long Island in Boston Harbor. The advantages of the site in Roxbury are, that the building is already erected, that it lies within the city limits, and that with it no unpleasant associations are connected. Within the last few years a modern hospital, in the best sense of the word, for chronic disease has been in operation on Long Island; through an unfortunate terminology this has been known as the Almshouse Hospital, entrance to which requires the formal declaration of pauperism. The injustice of this is apparent, a fact which will no doubt in due time be recognized by the law as well as by individuals. In the meantime it should be understood that it is proposed to treat essentially the same class of patients at the new hospital as are now being treated in considerable numbers at Long Island. The distinction of social status is a purely artificial one, and one which should wholly lapse when illness of any sort is under consideration. Long Island has possibilities for an almost ideal hospital of the proposed sort. There is fresh air in abundance, sun the entire day, adequate space for recreation and exercise; no infringement on the rights of neighbors, with consequent diminution in the value of real estate. More than this, there is already a hospital on the island, well equipped, with competent physicians and nurses, and the accessories which hospitals are more and more requiring. A new ward, primarily for the accommodation of tuberculous patients is about to be erected, on account of the increasing number of such patients who are calling for treatment. The natural query therefore comes: why not develop what we already have, rather than unnecessarily, as it would seem, multiply charitable institutions? Especially would this appear a wise policy in view of the manifest disadvantages of the Marcella Street Home, and the equally manifest advantages of Long Island. We have no desire, at this time, to discuss details; our purpose merely is, to direct attention to an institution and to a location which must not be ignored in the final determination of so important a question as the ultimate disposition of the city's indigent consumptives.

It is perfectly clear that provision for tuberculous patients everywhere, and particularly for those in an advanced stage of the disease, must be made in the immediate future. The question is one of national as well as local interest, and in the present state of the public mind we may look for a very marked general improvement in the care of these cases during the next decade.

How this is to be brought about, and how the problem as it applies to different localities is to be solved, experience must show. There can, however, be no doubt that the ravages of tuberculosis may be very materially checked by the establishment of suitable hospitals.

REPORT OF THE NEW YORK TENEMENT HOUSE COMMISSION.

THE report of the Tenement House Commission appointed last year, which was submitted to the legislature, with a special message by the Governor, on February 25th, is, as was to be expected from the fitness of the men composing the commission, a document characterized by ability, moderation and practicality. The most serious evils met with in the investigation, the report states, were insufficiency of light and air, due to narrow courts and airshafts, to undue height of houses, and to the occupation of too great a proportion of lot area, danger from fire, lack of separate water-closet and washing facilities, overcrowding and foul cellars and courts. With all the remedial legislation and regulation since the enactment of the first tenement house law in 1867, the present type of tenement house — the six-story "double-decker" — occupying 75% of a 25 foot lot, with four families on a floor, gives to its occupants less light and less comfortable surroundings than the average tenement of fifty years ago. The commission recommends that the narrow so-called airshaft be absolutely prohibited in all future tenement houses, that proper courts, sufficiently large to secure adequate light and ventilation, be required, and that the height of non-fireproof tenements, except where the building has a width of 40 feet or more, be limited to five stories.

The present tenement house laws are very inadequately enforced, as is shown by the fact that out of 330 tenements in course of construction in the Borough of Manhattan, inspected by the commission, only 15 were found in which there were no violations of the law. In the other boroughs there was no such house found. This state of affairs is largely due to the fact that the enforcement of the different laws in relation to tenements is divided among the four departments: Health, Building, Fire and Police. The commission is, therefore, of the opinion that the best solution of the present and future tenement house problem will come through the creation of a separate department, charged with no duty except the supervision of tenements, in which there should be various bureaus with specific functions. In one of the bills accompanying the report it is provided that the proposed department shall have at its head a single commissioner, who shall have entire control of its management and be held individually responsible for any violation of the tenement house laws. The opinion is expressed, furthermore, that a requirement to the effect that no tenement house shall be occupied for living purposes until a certificate for its completion in compliance with the law be issued, will not only enforce obedience to law in the simplest manner, but will do away with the present cumbersome system of threatening prosecution and the dragging on of long legal proceedings in civil actions.

The three bureaus recommended for the new department are those of building, of sanitary inspection, and of records. The object of the last named would be to keep the records of every tenement house in such a way that the commissioner could ascertain at any time all the facts in reference to any one house. In reference to the desirability of such a bureau the report says: "The commission finds that there are a number of houses in the city which are permanently infected with tuberculosis, and that families moving into such houses without knowing these facts have become infected with the disease. Dr. Biggs, of the Department of Health, shows in a special report on this subject, which forms part of the report, that in one block in one part of the city there are at least three tenement houses in which have occurred twenty-two cases of tuberculosis in each house within five years." In regard to baths, the commission states that ordinary commercial considerations are likely to settle this question in the near future, as an inspection of new tenement houses has shown that a large percentage of them have a private bath for each apartment. The report recommends that streets in tenement districts should be paved with asphalt, on account of the facility with which they can be kept clean, and suggests that small parks in such districts could be obtained at comparatively little expense by taking only the interior of a block and permitting the erection of model tenements upon the two exterior strips abutting on the streets. By adopting this plan the city would be able to obtain needed parks and recreation grounds, and new tenements could be constructed to accommodate, at remunerative rents, quite as many persons as are now inadequately housed by old tenements on the old area.

MEDICAL NOTES

PLAGUE AT CAPE TOWN. — Plague has definitely appeared at Cape Town, and a considerable number of cases have been reported. The *Medical Press* comments on the situation, as alluded, namely, that the plague had broken out ollows: "The sinister rumor to which we have in South Africa, has proved only too well founded. Should the disease be conveyed to the front the results may be of a terrible nature. The heavy mortality from enteric fever shows that the sanitary environment of the troops must be utterly defective in the elementary points of wholesomeness. If enteric fever can play such havoc, what

may we expect from plague? Both maladies are "filth diseases," and the bad sanitation that fosters the one will extend an equal shelter to the other. The difficulties of the situation, indeed, appear to be increased a hundredfold by the invasion of the Asiatic pest. Should the plague have already broken out among the British troops it is to be hoped that the home authorities will lose no time in announcing the fact. The news that the disease had reached South Africa came to London first by way of the newspapers of Paris and Berlin. That information has now proved correct, and there is no particular reason, so far as can be seen, why the War Office should not confirm or deny the further Continental rumor that the pest has already killed a number of our soldiers. What is to be gained by silence? Has the War Office taken any steps to furnish ample supplies of plague serum in case of such an outbreak at the front?

In Union is Prosperity. — It is reported that surgeons at Vienna had made preparations to operate upon and separate Barnum's Siamese twins — thirteen-year-old boys — exhibited there, when relatives interfered. They claimed that the twins were prosperous together; apart they would be penniless.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, March 6, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 89, scarlatina 33, measles 50, typhoid fever 3.

Growth of the Children's Hospital, Boston. — The following statistics from the recent Children's Hospital report are of interest in showing the remarkable development of the institution: In 1890 the number of patients treated in the wards was 442, and in 1900 it was 1,394. In 1890 the new cases in the Out-Patient Department were 1,712, and in 1900 2,586. In 1890 the visits to the Out-Patient Department were 7,291 and in 1900 21,436, while of visits for out-door relief there were none in 1890, but in 1900, the value of this extension of the hospital service having been fully proved, there were 1,828 house visits made by members of the hospital staff and nurses. In 1889 the Convalescent Home, at Wellesley, cared for 104 patients, and in 1900 for 440 patients. In 1890 the number of nurses in the hospital was only 10, while in 1900 the average number has been 35.

Statistics of Butler Hospital, Providence, R. I. — According to the recently issued report of the Butler Hospital for the Insane, at Providence, R. I., on January 1, 1901, there were in the hospital 186 patients, 92 men and 94 women. There were admitted during the year 63 patients, 29 men and 34 women. The whole number of patients under treatment during the year was, therefore, 249. The daily average population was 174. There were discharged 78 patients, 40 men and 38 women. Of this number 13 had recovered, 14 had improved, 22 were unimproved, 4 were not insane, and 25 died. There remained at the close of the year 171 patients, 81 men and 90 women.

House of the Good Samaritan, Boston. — During the past year this hospital has received and cared for 241 patients, of whom 73 were children.

A Case of Smallpox in Somerville, Mass. — It is reported that a case of smallpox has been discovered in Somerville, Mass. The patient is said to have come from Cleveland, Ohio, during the active stage of the disease. The Board of Health has urged immediate general vaccination.

A Smallpox Hospital in New Hampshire. — Owing to the prevalence of smallpox in and about Concord, N. H., the State Board of Health has opened a special hospital for the care of patients suffering with the disease at Harrisville.

New Hospital for Lynn, Mass. — The Union Hospital of Lynn has bought an estate in that city consisting of a house containing twenty rooms, and a lot of land with an area of 25,000 square feet. The building is in condition for immediate occupancy, but improvements will be made before patients are received. Forty patients can be cared for in the several private rooms and the two large wards. An Out-Patient Department is part of the plan of work, which will probably be located in the centre of the city.

NEW YORK.

Hearing on the Seymour Bill favoring Osteopathy. — On February 27th there was a hearing before the Assembly Committee on Public Health on the Seymour bill conferring on osteopaths the same privileges now possessed by licensed physicians, and among those who spoke in favor of it was Mark Twain, who made a long address in behalf of what he called "personal liberty." Among those who argued against it were Dr. Didama of Syracuse and Drs. Van Fleet and Robert T. Morris of New York. Dr. Van Fleet contended that the enactment of such a measure would flood the State of New York with quacks and incompetent practitioners, and would be both a gross injustice to licensed physicians and a discrimination against the regularly incorporated medical colleges of the State. No one, he said, would care to take a four years' course at a medical college if he could go to some

Western osteopathic school, and in that way gain the right to practice medicine in New York. Dr. Morris gave the osteopaths some rather hard raps. In the course of his remarks he read from one of their authorities the treatment prescribed for felon which consisted in moving the muscles of the affected finger. "The value of that treatment will be readily appreciated," said he, "when I tell you that there are no muscles in the fingers." Later on he quoted from the osteopathic treatment of locomotor ataxia, which embraced the manipulation of bones claimed to be out of place. At this point Dr. Morris produced the spine of a child, and, taking hold of one of the vertebræ, challenged any one of the osteopaths present to move a part of the bone the fraction of an inch. "Now, there are the gloves, gentlemen," he exclaimed, "come, put them on, and give us an exhibition of your professed skill." The challenge, it is needless to say, was not taken up.

A WEDDING BY PHONOGRAPH. — A novel wedding recently took place in the town of Union, near Binghamton, N. Y., where the difficulties of a strict quarantine were ingeniously overcome, and, notwithstanding the illness of the bride, the ceremony was performed on the day originally set for it. Miss Rockfellow of Chicago, and H. A. Bush of West Point, Ky., had planned to be married at the home of the former's sister in New York, but while on her way East the bride was attacked with diphtheria at Union, where she had stopped for a brief visit with friends. The bridegroom was summoned, and he conceived the idea of a phonographic wedding. Two phonographs were procured, and in one of these the clergyman's questions and Mr. Bush's answers were recorded. The cylinders were then transferred and the machines sent to the bride in her sick chamber. When they were set in motion she answered the questions asked through one machine into the mouthpiece of the other.

THE ANOMALIES OF CHRISTIAN SCIENCE. — The *New York Herald* is authority for the statement that the husband of Mrs. Augusta Stetson, the leader of the Christian Scientists in New York (who is second in authority and influence in the sect only to Mrs. Eddy, and who derives an income from "healing" and instructing others variously estimated at from $10,000 to $100,000 a year), draws from the government, as a Civil War pensioner, a monthly stipend of $72 "for rheumatism and paralysis." According to the newspaper account, the husband is a helpless invalid, confined to the house, and in the same residence is Mrs. Stetson's mother, who is also a sufferer from rheumatism and attended by a trained nurse.

ACQUITTAL OF BELLEVUE HOSPITAL NURSE. — Jesse Davis, the pupil nurse charged with causing the death of Louis Hilliard in the insane wards of Bellevue Hospital, was acquitted on February 28th, after a trial lasting three weeks. The principal witness for the prosecution, Minnock, a reporter who feigned insanity in order to gain admission to the wards, gave his evidence in such a way that even the prosecuting attorney discredited it, and two other witnesses were insane patients, whose testimony was necessarily open to doubt. It is said that the indictments against the other two nurses charged with the same offense will now be dismissed.

POLLUTION OF BROOKLYN WATER SUPPLY. — At the annual meeting of the Medical Society of the County of Kings, held February 25th, the Committee on Public Health, of which Dr. E. H. Bartley is chairman, reported that a portion of the water supply system of Brooklyn is polluted, and resolutions offered by the committee were adopted, urging upon the Health and Water Departments the necessity of the sanitary patrol of the entire water-shed, as provided for by the city charter, and of the early construction of a grand filtration plant for filtering the whole supply.

SMALLPOX. — During the month of February there were reported in the boroughs of Manhattan and the Bronx 97 cases of smallpox, against 59 in January. In Brooklyn, also, the disease has been increasing. On February 27th 8 cases were discovered in three adjoining tenement houses, and on March 1st 11 cases occurred in a single large house.

APPOINTMENT OF STATE HEALTH COMMISSIONER. — Governor Odell has appointed Dr. Daniel Lewis, of New York, State Health Commissioner, to serve until December 31, 1904. The functions of the commissioner are the same as those of the recent State Board of Health, of which Dr. Lewis has been president since 1895.

GIFT TO POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL. — The Post-Graduate Medical School and Hospital has received an anonymous gift of $15,000, from a friend of the institution, for the purpose of supporting in perpetuity three beds in the babies' wards of the hospital.

Miscellany.

INFORMATION FOR CANDIDATES SEEKING EMPLOYMENT IN THE ARMY.

As a result of the reorganization of the Army by Act of Congress approved February 2, 1901, there are 129 original vacancies as assistant surgeon to be filled.

The prescribed age limit of candidates will be

rigidly adhered to, and it will be useless for those who are more than twenty-nine years of age to apply, unless they have had previous service as mentioned in the circular. The requirement of hospital experience or its equivalent in private practice will also be insisted upon. Hospital work as a student will not be regarded as fulfilling this requirement; experience as a physician after graduation is what is meant. Two years of private practice will be considered an equivalent of one year's hospital experience.

Army medical boards will be convened at an early day in Washington and in San Francisco, and examinations will be begun as soon as possible.

Copies of a "Circular of Information" may be obtained upon application to War Department, Surgeon General's Office, Washington.

The Medical Corps of the Army, as increased from a total of 192 to 321 medical officers by recent Congressional action, consists of a surgeon general with the rank of brigadier general, 8 assistant surgeons general with the rank of colonel, 12 deputy surgeons general with the rank of lieutenant colonel, 60 surgeons with the rank of major, and 240 assistant surgeons with the rank of first lieutenant, mounted, for the first five years, and the rank of captain, mounted, thereafter, until promoted to major.

Section 1172, Revised Statutes of the United States, provides that "No person shall receive the appointment of assistant surgeon unless he shall have been examined and approved by an army medical board, consisting of three surgeons or assistant surgeons, designated by the Secretary of War; and no person shall receive the appointment of surgeon unless he shall have served at least five years as an assistant surgeon in the regular army, and shall have been examined and approved by an army medical board, consisting of not less than three surgeons, designated as aforesaid." The act to increase the efficiency of the military establishment of the United States, recently approved, further provides "that the period during which any assistant surgeon shall have served as a surgeon or assistant surgeon in the Volunteer Army during the war with Spain or since shall be counted as a portion of the five years' service required to entitle him to the rank of captain.

All vacancies are filled by appointment to the junior grade (first lieutenant). Promotion through the intermediate grades of rank from that of captain to that of colonel is by seniority, but there is an examination for the rank of captain and another for that of major, to ascertain the fitness of the officer for promotion. Advancement to lieutenant colonel and colonel takes place without further examination. The surgeon general is selected by the President from among the members of the corps.

The physical examination comes first in order, and must be thorough. Candidates who fall below sixty-four inches in height will be rejected. Each candidate is also required to certify "that he labors under no mental or physical infirmity or disability which can interfere with the efficient discharge of any duty which may be required." Errors of refraction, when not excessive, and not accompanied by ocular disease, and when correctible by appropriate glasses, are not causes for rejection.

The professional examinations are conducted by both written and oral questions, upon anatomy, physiology, chemistry, hygiene, pathology and bacteriology, therapeutics and materia medica, surgery, practice of medicine, obstetrics and the diseases of women and children. Examinations are also conducted at the bedside in clinical medicine and surgery, and operations and demonstrations are required to be made by the candidate upon the cadaver.

Hospital training and practical experience in the practice of medicine, surgery, and obstetrics are essential to candidates seeking admission to the Medical Corps of the Army, who will be expected to present evidence that they have had at least one year's hospital experience, or the equivalent of this in practice.

Obituary.

GEORGE H. BIXBY, M. D.

Dr. George Holmes Bixby died in Boston, February 26th. He was born in 1837 at Parimaribo, S. A., where his father was United States Consul. He received his education at Williams College and at the Dartmouth and Harvard Medical Schools. He also studied in Vienna and Paris. He served in various capacities throughout the Civil War. Later he took up gynecology as a specialty and was associate founder and editor with Dr. Horatio R. Storer of the *Gynecological Journal*, was a member of various medical societies and contributed many articles to medical journals. His later years were spent in a condition of invalidism, which prevented the active practice of his profession. He leaves one daughter.

Correspondence.

AN EXPLANATION FROM THE MASSACHUSETTS GENERAL HOSPITAL.

Boston, March 4, 1901.

Mr. Editor: — In your issue of February 28th you published a communication entitled "Should a Hospital Charge for Information about Patients?"

For the benefit of your readers, I wish to say that the Massachusetts General Hospital does not plead guilty to the charge of receiving money for giving information about patients to the physicians who send them here.

If a physician has asked for a *full copy of the record* of a patient, a charge has sometimes been made for making the copy. Your correspondent did not ask for a full copy and the bill was sent to him through a clerical error. If the same thing has ever happened to any other member of the profession, I shall be glad to have him communicate with me on the subject.

Very sincerely yours,

Herbert B. Howard,
Resident Physician.

METEOROLOGICAL RECORD.

For the week ending February 23d, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Deaths reported 2,481; under five years of age 702; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 585, acute lung diseases 427, consumption 265, diphtheria and croup 72, diarrheal diseases 44, scarlet fever 36, influenza 27, typhoid fever 9, whooping cough 11, measles 14, cerebrospinal meningitis 12, smallpox 9.

From whooping cough New York 3, Pittsburg 4, Providence, Boston, Somerville and Holyoke 1 each. From cerebro-spinal meningitis Worcester 4, Lynn 2, Boston, Somerville, Gloucester, Lawrence, Brookline and Fitchburg 1 each. From scalet fever New York 24, Boston 7, New Bedford 2, Baltimore, Springfield and Taunton 1 each. From typhoid fever New York 5, Baltimore, Boston, Cambridge and Haverhill 1 each. From measles New York and Pittsburg 5 each, Boston 4. From smallpox 9 cases in New York City.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,789,099 for the week ending February 9th, the death rate was 19.8. Deaths reported 6908; acute diseases of the respiratory organs, (London) 397, whooping cough 129, diphtheria 101, measles 57, fever 44, diarrhea 40, scarlet fever 26.

The death rates ranged from 12.3 in Cardiff to 29.5 in Norwich: Birkenhead 17.5, Birmingham 20.2, Blackburn 18.4, Bolton 15.1, Bradford 15.1, Brighton 24.2, Bristol 21.5, Burnley 18.6, Croyden 12.4, Derby 17.6, Gateshead 20.4, Halifax 20.0, Leeds 19.6, Leicester 16.2, Liverpool 27.9, London 18.7, Manchester 24.7, Nottingham 21.4, Plymouth 22.6, Sheffield 20.0, Swansea 21.4, West Ham 14.4, Wolverhampton 19.6.

RECENT DEATHS.

THOMAS RILEY, M.D., M.M.S.S., of Adams, died March 4, 1901, aged fifty-seven years.

THEODORE GIDDINGS, M.D., M.M.S.S., died in Housatonic, December 28, 1900, aged sixty-four years.

FREDERICK LYMAN THAYER, M.D., M.M.S.S., died in West Newton, March 4, 1901, aged fifty-three years.

DR. ABBOTT HODGMAN, of New York, died on February 26, from cardiac disease, in the sixty-ninth year of his age. He was born in West Townsend, Mass., on November 15, 1832. He studied for a time at the Dartmouth Medical College, and was graduated from the Medical Department of the University of the city of New York in 1858. In 1859 he was attached to the hospital staff on Blackwell's Island, and afterwards was in charge for eight years of the Medical Department of the city's prisons. He had practiced in New York for over forty years.

BOOKS AND PAMPHLETS RECEIVED.

Malaria and Mosquitoes on the West Coast of Africa. By Dr. Hans Ziemann, Staff Surgeon, late Government Physician in Camaroon. Reprint. 1901.

A Medico-Legal Manual. By William W. Keysor, Lecturer on Medical Jurisprudence in the Omaha Medical College, etc. Omaha: Burkley Printing Company. 1901.

State Laboratories as Aids to Sanitary Work. By Samuel W. Abbott, M.D., Secretary of the Massachusetts State Board of Health. Portland, Me.: Marks Printing House. 1901.

Notes on some Affections of the Heart Substance, with Illustrative Cases. By Thomas E. Satterthwaite, M.D., Consulting Physician to the Post-Graduate Hospital. Reprint. 1901.

New Points in the Anatomy, Histology and Pathology of the Rectum and Colon. By J. Rawson Pennington, M.D., Professor of Rectal Diseases, Chicago Policlinic, Chicago. Reprint. 1901.

The Prognosis of Various Types of Albuminuria. By Talbot Jones, M.D., St. Paul, Minn., Visiting Physician to the City and County, St. Luke's and Bethesda Hospitals, etc. Reprint. 1900.

Resultate der Bottini'schen Operation bei Prostatahypertrophie. Demonstration eines gemeinsam mit Dr. Bierhoff construirten kystoskopischen Prostata-Incisors. By Dr. Albert Freudenburg, Berlin. Reprint. 1901.

Asthenic Bulbar Palsy. By Charles W. Burr, M.D., Neurologist to the Philadelphia Hospital, and D. J. McCarthy, M.D., Associate in Clinical Medicine in the William Pepper Laboratory of Clinical Medicine. Reprint. 1901.

An Atypical Case of Multiple Sclerosis. By Charles W. Burr, M.D., Neurologist to the Philadelphia Hospital, and D. J. McCarthy, M.D., Associate in Medicine in the William Pepper Clinical Laboratory of the University of Pennsylvania. Reprint. 1900.

Medical and Surgical Experiences in the South African War. By Lieut.-Col. G. Sterling Ryerson, M.D., lately British and Canadian Red Cross Commissioner with Lord Roberts' Headquarters in South Africa. St. Louis: Lambert Pharmacal Co. 1901.

Address.

THE STORY OF THE BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.[1]

BY J. G. MUMFORD, M.D., BOSTON.

THE story of the Society for Medical Improvement is not so much a history as it is a series of biographies. As a history, it is commonplace enough, and interests us because it runs back nearly three-quarters of a century, and contains the names of a good many well-known men. Indeed, we may divide its life into three generations. To do so gives it a rather personal and family interest. A number of us can actually point to a grandfather among the early members. It is none the better for this, perhaps, but it is better than most societies, I believe, and I hope to show some reason for this belief. Its history has been sketched briefly more than once before. They used to have anniversary dinners in the old days, when men would talk, sing songs and poetize. The story of the founders was often told. On the fortieth anniversary, Dr. Spooner, a surviving founder, wrote a letter about it. That we have. In 1880 Dr. J. C. White made a careful and concise statement of the aims and the work accomplished; and in 1894 again there was an overhauling of accounts, when the Observation Society joined us; but now we are at the beginning of a century, and setting up in a beautiful new hall, so that I am moved to write down in some sort of order the tale of the years that are past, and of the men who lived through them.

It is easy to think of the life of this society as composed of three generations, and it is a rather striking fact that with the passing of each generation there does indeed appear a new era. First there were those ancient men, our professional grandfathers, with their limited ideas of science as we know it; their strenuous gropings in the dark; their earnestness in small things; their blind pathology; their empirical therapeutics; their almost pathetic struggling toward the light. Then there came the second generation, growing out of this first one, the adolescence, the development of it, as it were. The sudden leap forward is amazing, even to one reading these stately old Records of ours. In ten years' time, from 1845, a whole new vocabulary appears. First there came statistics. Then there came the microscope; then there came ether; then there came a burst of scientific enthusiasm and progress such as, up to that time, the world had never seen. This second period, the period of our fathers, extended down to our own time. It saw the development of anesthetics, and of the new pathology. It lived through the Civil War. It reaped the benefit of the great forces which made neighbors of the most distant scientific communities, and stimulated the expansion of modern knowledge.

[1] Being the Story of the Society, read January 21, 1901; the occasion, the opening of Sprague Hall in the new Medical Library Building, The Fenway.

And so we come down to our own era. What shall we call it? Many great names claim it — Listerism or Pasteurism; or the Age of Antiseptics; or Bacteriology — whatever else it may be, it is certainly the age of surgical expansion. And to no age has belonged more pre-eminently the motto, *Magna est veritas et prevalebit.* It is through all this, as it was manifested here in Boston, that the Records of the Improvement Society lead us.

There is no mystery or tradition about the beginnings of this society. It started in full-fledged, with a beautifully-written constitution and by-laws, on the 19th of February, 1828. There were eleven members. They met at the house of Dr. John P. Spooner, and they proceeded to organize themselves into a society with as much solemnity and earnestness as the Federal delegates from the thirteen States. Years afterwards Dr. Spooner used to say that he started the society. At any rate, it was a Boston affair, pure and simple. It was not the outgrowth of French ideas, as was the Observation Society, started later. Eleven young gentlemen, recently established in the practice of medicine, (on the suggestion of Drs. Spooner and John Ware) thought they would meet together on a sort of medico-social basis twice a month. These gentlemen were Zabidiel B. Adams, John P. Spooner, George W. Otis, Jr., Joshua H. Hayward, D. Humphreys Storer, Horatio Robinson, James M. Whittemore, J. G. Stevenson, Joseph W. McKean, Enoch Hale and John Ware. To this company were added fourteen others in the course of the year. So with a membership of 25 the society began its career. James M. Whittemore was the secretary, and his beautifully kept records run through the early months of the society's life. In those days the proceedings were delightfully informal, as one would expect. The men were mostly young and well known to each other; there was no president, or permanent chairman. There were no regular written papers, as has been the custom for so long now. When the members met together, each apparently bursting with his desire to impart knowledge, they were called on in alphabetical order for their communications; and to judge from the written record, each man availed himself of his opportunity.

The first regular meeting for the discussion of medical topics was held on the 10th of March, 1828, and Dr. James D. Stevenson opened the highly important proceedings of this society, which have gone on for seventy-three years.

Dr. Stevenson's proposition was this: In the case of a child born while the mother is in a standing position, with rupture of the cord, "Is there any special danger to mother or child?" They began by having a regularly appointed subject for discussion, in addition to the more informal communication, and the first important topic was, "What are the earliest diagnostic symptoms of croup?" And these two topics, the one obstetrical, the other dealing with infectious diseases, have been always the leading topics of

discussion throughout the life of the society. On this first evening the conclusions were that the croup subject was an interesting one, and that it should be continued at the next meeting. Out of this custom of calling on members alphabetically grew the practice of recording accurately the attendance at each meeting; so that to this day the actual attendance at every individual meeting for seventy-three years is on record.

Two other events of interest connected with the society occured in this year of 1828: The starting of the Anatomical Cabinet by the society, and the founding of the *Boston Medical and Surgical Journal* by gentlemen who were members of the society. The cabinet was an ambitious project. It continued to grow for many years. It was fostered mostly by the enthusiasm of one man; it published a printed catalogue; and it lies buried in the Warren Museum of the Harvard Medical School. The *Boston Medical and Surgical Journal* was not an original endeavor. It arose out of two other journals — the *New England Journal of Medicine and Surgery* (1811), and the *Boston Medical Intelligencer* (1823), which were consolidated under its name; and it owed its initial success to the editorial endeavors of Walter Channing, J. C. Warren and John Ware.

During those early years members of this society met at each other's houses, and owing to this agreeable arrangement, doubtless, I find that the total expenses of the society for the first year were $7.50. It soon became evident to our progenitors that a more systematic method of work would improve the meetings; and with that in view, standing committees were appointed, whose duties were to present reports on divers topics of medical interest. In the same year of 1829 the society resolved to publish Transactions. These ambitious extensions in no long time brought about the necessity for larger accommodations. Therefore, in 1830, two years after the founding, a room was hired for the meetings, and for the cabinet, over the shop of Smith & Clark, druggists, on Washington Street, the price paid being $25 a year. In those new surroundings there seems to have been the same difficulty in finding readers of formal papers that we sometimes experience now; so that it was even found necessary to impose a fine of $2.00 for failure to read.

As one plunges through the sea of old Records one is constantly tempted to seize upon some fine old medical name, bring it to the surface and exploit it. One could gossip for days about those old times and men and things. I will mention a few of the men in their order. There were those who founded the society, whom I have named. Then in 1829 came John Homans, Sr., John D. Fisher and Francis G. Higginson; 1831, John B. S. Jackson; 1832, Charles T. Jackson and Joseph Roby; 1833, Charles G. Putnam and John C. Hayden; 1834, Henry I. Bowditch; 1835, Henry G. Clark and J. Mason Warren; 1836, George C. Shattuck, Jr., Oliver Wendell Holmes and George H. Bethune. In 1837 this society of young men took unto itself as honorary members three distinguished gentlemen of a former generation: George C. Shattuck, Sr., James Jackson, Sr., and J. C. Warren; in 1838, Jacob Bigelow as a regular member, and Edward Reynolds, S. D. Townsend and Jeffries Wyman; in 1839, Samuel Parkman. I believe every one of these names is well known to all of us, and to the older members of the society must call up a flood of interesting reminiscence and anecdote. Now there is a curious thing about the steady, undeviating progress of this association of ours — it is ever unemotional, unruffled by stirring events and men. Though Charles T. Jackson and J. C. Warren and Henry J. Bigelow were members, the discovery of ether raised scarce a ripple in their debates. These men themselves, and their sons and brothers, went into the army and navy in war times. Yet this is all the official note we see, written three months after the fall of Sumter, that, "owing to the disturbed political condition of the country, the society judges it wise that the meeting of the American Medical Association be postponed for one year." And through all this time, in its quiet way, the machinery of the society and its habits and its traditions were gradually crystalizing. The first prudential committee is mentioned as a creation of 1837. It consisted of Messrs. Ware, Fisher, Gould, Palmer and Roby — five in all; a committee of five it has remained ever since. For more than forty years its duties seem to have been largely perfunctory, certainly not onerous, consisting for the most part in approving the names of candidates for membership. And during all those former years it was composed of some of the oldest members of the society — Dr. Jacob Bigelow and Dr. D. H. Storer served until extreme old age; also Dr. Ware and Dr. Gould for many years.

Dr. Jacob Bigelow was constant in his attendance at the society meetings. Already of mature age, vast experience and deeply learned in the natural sciences, his presence was a great stimulus to his younger companions; and, unlike his distinguished son, he elicited, rather than depressed discussion. In that first era, which for convenience is limited to the years before 1846, one of the most conspicuous figures was Dr. Oliver Wendell Holmes. For two years he was secretary, and the volume of his records, in his beautifully precise, feminine handwriting, makes glad the eye of the reader as much as his quaintly delicious phraseology warms and uplifts the heart.

I suppose that to the older members among us the name of Dr. J. B. S. Jackson, more than that of any one man, stands for the work of this society. Elected to membership three years after the small beginnings of 1828, he continued active in his interest until 1879, only twenty-two years ago, and during all these forty-eight years his enthusiasm in the study of morbid anatomy seems never to have flagged. Wherever one opens the old Records, there will be found a paragraph devoted to Dr. J. B. S. Jackson and his unfailing specimen. And, especially in the first twenty years

of the society's life, his enthusiasm for the autopsy room might be described in the gamin language of today as something fierce. Of course, in those days, pathological surgery supplied little material, and it is a curious commentary that when one reads in the Records of one day some surgeon's clinical account of a desperate case, one may expect to find in a subsequent Record *not* the story of the operation, but Dr. J. B. S. Jackson's account of the autopsy. Indeed, in those early years, the number of morbid specimens shown was astonishing.

The vigorous growth of the young society suffered little abatement up to the time of the Civil War. It was small, as we reckon figures; it was somewhat exclusive; it was composed of busy workers in all fields of medicine; it afforded them all their equal and almost their only opportunity for speaking and publishing. It printed "transactions," it represented teachers, practitioners and hospital staffs; and in a very real sense it controlled the practice and the medical fortunes of this community. In the very early years, social features of these meeting were not lacking. The members celebrated an anniversary day in February; and annually, for about twelve years, dined together at each others' houses. Here is Dr. Holmes' account of one of these gatherings: "The Anniversary Meeting of February 7th, 1838, Dr. Ware in the chair. At 7 o'clock the society disposed itself at table, animated by the presence of the dinner, which, by its outward arrangement and intrinsic excellence, did honor to the taste and judgment of its providers. Dr. Roby favored the society with an ingenious, pointed and witty address, touching the peculiar disposition of the mind required on entering on the study of medicine, and the effects which the practice of this society exercises upon our intellectual and social condition." Dr. Holmes then read a poem. "No incident occurred to interrupt the festivities of the evening, with the exception that a couple of our most efficient members were interrupted for a short time by accidents too frequent on these occasions. An amiable indiscretion, dating undoubtedly from some bright May morning, was visited upon the heads of Drs. Ware and Adams, by a midnight call into the midst of a February snow storm. The hilarity of the company was temporarily diminished, and the census of the city permanently increased during their absence."

So the society was small, more like a club. Of the 35 members, usually 25 attended. Admission to membership was difficult. All were friends. The minutes, written with the greatest care and detail, covering sometimes eight or ten pages of a large sheet, give an idea of the daily life, pursuits and purposes of the various members; allowing, of course, for the point of view of the individual reporter. But there is no disguising that ancient courtesy of the formal type, which we expect and which still lingers obscurely among us; known better, perhaps, to our profession than to others. The spirit of these ancient times still pervades the pages, and as one reads, the men themselves become very real and present.

These social features and small friendly gatherings did not last many years. After 1840 the record of anniversary dinners ceases, though an occasional sporadic festivity occurred from time to time thereafter. The nineteenth anniversary of the founding was celebrated at the house of Dr. Reynolds, and a poem was read by Dr. Holmes. And again, more than twenty years later, on the fortieth anniversary of the founding, a very real and serious jubilation took place. Dr. D. Humphries Storer, an original member, and now growing old, entertained the society at his house. Doubtless some of our present members recall the occasion. A delightful account of the evening is given in the Records, and a copy of a letter from Dr. Spooner, then living, in which he tells the story of the founding. But after all, social matters have concerned us little for the last sixty years. It was toward the end of this first period in our history, August 14, 1843, that a gentleman was elected who is now, and has been for many years, the Nestor of this society, Dr. Samuel L. Abbott. His sponsor was Dr. Storer. Dr. Samuel Cabot, Dr. G. Wiley and Dr. William S. Coale were elected in the same year, and their names seem to carry us back to a very early era. Besides being a scientific and social society, this organization attempted to meet other needs in those early days. It was a journal club. It started a library. It collected a museum. And in other ways that I have named, it flourished as a centre of medical life in Boston.

. . . . . .

The second era or generation in the life of our society is so full of interest, and to many of us is so familiar, either by experience or story, that it is not easy to condense it into a few dry words. I have characterized it as the age of ether. It was that; it was much more. Strong names blazon its course, many of them coming down through the years. At the very beginning of it, and perhaps more conspicuous than any other one man, comes Henry J. Bigelow — leaping upon the stage, as it were. That capital piece of memoir writing, I think the very best medical biography known to me, Hodges' Life of his great colleague, has reached us recently, and the tale he tells of Bigelow's career renders futile my feeble words here. But there were others: Samuel Cabot, Jeffries Wyman, Clark, Lyman, Townsend, Gay, Derby, Minot, Williams, Thorndike, Homans (John and Charles), Hodges, Borland, Reynolds, White, Green, Blake, Channing, Cheever, and more if one were so minded; for who may say what name will live through this and future generations? Certain names, then, and certain events dominate the Record: following the years, one sees a man's entrance, his feeble beginnings, and his increase in force and courage. Then his youthful modesty thrown aside, his earnest setting forth, his dominating tone; and then suddenly, mostly, he disappears from our pages. In the first era it was Storer and Ware, James Jackson,

J. C. Warren, Jacob Bigelow who successively engrossed us. Now these names cease mostly, and Henry J. Bigelow, J. Mason Warren, Cotting, Calvin Ellis, George C. Shattuck and their like hold the stage. And through it all, year in and year out, generation after generation, sounds the steady, persuasive voice of J. B. S. Jackson — pathologist, scholar, teacher. Through many of these years, the clerkly hand of William M. Morland traces the Record — a name now only to most of us; notable to me for the scolding given him by Henry Bigelow, asserting that his part in the discussions was constantly inadequately reported; the careful scribe, himself, bearing witness to the chastisement. Thereafter Dr. Bigelow's words were most faithfully and accurately recorded.

I have mentioned the all-embracing functions of the society. Until near the beginning of this era it was the only one of its kind. The programme of each evening we should consider enormous in variety and extent. Here is a sample day, taken from the Records of 1848. In addition to numbers of pathological specimens, presided over by J. B. S. Jackson, the programme read: (1) "Oil from Fatty Liver," (2) "Frogs with Additional Extremities," (3) "Diverticulum from Small Intestine," (4) "Intestinal Calculus from a Horse," (5) "Cast of Thorax to show Cardiac Enlargement," (6) "Necrosis after Amputation," (7) "Compound Fracture of Thigh," (8) Cauterization in Croup" (oral), (9) "Double Urethra," (10) "Convulsions in Typhoid," (11) "Fatal Hemorrhage in Dysentery," (12) Abscess of the Ear," (13) "Asiatic Cholera."

Now, as early as 1845, Henry J. Bigelow's voice was heard in this assembly, and the next year he began to publish that series of papers on ether, scarcely mentioned here, which gained him so great a notoriety. Other gentlemen, conspicuous in the ether controversy, were members of this society at the time; notably, J. C. Warren and Charles T. Jackson. Of them we hear not at all on this subject. George C. Shattuck was secretary then, and a careful reading of his elaborate Minutes gives no inkling of the raging of the etherial storm. In November, 1846, it is recorded that "Dr. H. J. Bigelow read a paper on the recent discovery and practice of the inhalation of a vapor so as to produce insensibility during the performance of surgical operations and the extraction of teeth." The amazing fact in regard to this famous communication is not a rising storm of criticism and interest, or any slightest evidence of appreciation of what it all meant, but that the communication was dismissed with a few languid comments by Drs. Hayward and Hale on the propriety of hospital surgeons using a secret remedy, as Morton's "letheon" then was.

. . . . . .

After Henry Bigelow and J. B. S. Jackson, the most conspicuous contributor to the meetings of this middle era was J. Mason Warren. His remarks were nearly always on surgical cases — many of them of great interest thoughtfully and forcefully presented. To judge from the accounts in the Records, Dr. Warren must have taken a keen interest in curious and unusual subjects; freaks of Nature, monstrosities and the like, were collected and reported by him. He showed the society the Scotch Giant and the Aztec Children, and among other surprising cases, reported at length this one of extraordinary fecundity: A woman living at 100 West 27th Street, New York City, gave birth in 1858 to a boy; July 30, 1859, boy and girl; March 29, 1860, boy and girl; March 1,1861, two boys and one girl; February 13, 1862, two boys and two girls — twelve children within five years; and they all lived.

It would be extremely interesting to take any single subject, or series of cases, and trace it through these eighteen volumes of Records: Erysipelas, puerperal fever, the radical cure of hernia, the treatment of ovarian tumors occupied successively the attention of the society, and as men and methods changed, came to be looked upon very differently, as we may suppose.

It is interesting, too, to note the repeated demonstration of the well-known medical truism that rare cases seldom come singly: Dr. Jacob Bigelow shows a thoracic aneurism; at the next meeting, Dr. Jackson shows two. Dr. Samuel Cabot reports a foreign body in the trachea; at the next meeting, Dr. Henry J. Bigelow reports another. Dr. Warren reports a death from chloroform; Dr. Bethune reports a second. Then there are to us the provokingly suggestive discussions hovering around some subject now made complete by scientific demonstration. The beginnings of bacteriology flash upon us as out of the Middle Ages; to be succeeded only by guesswork and darkness. In 1862, for instance, Dr. Jeffries Wyman reported observations on dust, and pointed out its composition as shown by the microscope; spores, hairs, minute eggs, pus corpuscles. And Dr. J. C. White said that while in Germany he had seen pus corpuscles from the air caught on plates in the hospitals. Then about the same time, the frightful extent of hospital gangrene in army hostitals exercised the profession, and the almost intelligent use of antiseptic dressings became especially noticeable. So it was with the recollection of these frightful surgical conditions fresh upon them, that American surgeons welcomed the principles of Lister, even more eagerly than did their European colleagues. The early carbolic method was urgently advocated in 1867 by Drs. George Derby, J. C. White and Upham; and Dr. John Homans spoke of the common use of permanganate of potash in the maternity wards at Vienna in 1865. Curiously enough, as illustrating the familiar scepticism, born of sad experience, Dr. Hodges heard with incredulity their enthusiastic claims. The inception, too, of many medical and surgical methods for long years familiar to us is seen to grow out of these debates: Dr. Samuel Cabot was the first to point out and insist upon the value of ether in the diagnosis of obscure abdominal tumors. Dr. J. B. S. Jackson repeatedly asserted the identity of diphtheria with

membraneous croup? Dr. Jacob Bigelow showed the value of the clinical thermometer in estimating the range and course of the temperature in typhoid fever. Dr. Coolidge urged the importance of carbolic acid and glycerine for preserving dissecting-room subjects. Dr. Fifield pointed out that a twisted ovarian tumor may be the cause of an acute peritonitis. And on January 11, 1864, Dr. H. G. Clark reported a successful case of ovariotomy with recovery of the patient. On the other hand, many of our younger members of the profession are apt to forget how extremely recent are some of our most important therapeutic agents. Thus in 1870, Dr. Francis Minot stated that the treatment for rheumatism was colchicum; the salicyllates being unknown; and in 1884 antipyrine and cocaine were suggested for the sake of their now familiar properties. What we call "teno-synovitis" is a condition in the daily experience of every out-patient surgeon; yet thirty-five years ago Dr. Fifield reported a case of painful crepitus in the tendons, and inquired into its cause and treatment. I suppose that no one surgical subject, after the discovery of ether, has attracted more wide-spread interest and controversy in our community than the disease which Dr. Fitz has called "appendicitis"—and the interest in this condition is by no means recent. Cases of tuphloenteritis appear on our Records so long ago as 1836. And towards the end of the second era in the life of the society Dr. J. B. S. Jackson presented a communication on the prevalence of this disease from 1840–1867. It had been asserted that the condition was more common in ancient times, but Dr. Jackson found in our Records the reports of 16 cases quite evenly distributed, and covering a period of twenty-seven years, an average of less than 5 a year.

Now, the two great events of this second era were the introduction of ether, and the Civil War. Their effect upon the lives and practice of our fathers must have been enormous; and if one could blot out this era, skipping from the year 1845 to the year 1868, the advance of Science in the interval would seem to us still more startling. Yet those two great events, as I have said, are little more than touched upon in the Records. Their overwhelming presence seems to have been so great, and their importance so obvious, that secretaries referred to them no more than they would have referred to the changes of the seasons.

Indirectly, however, the presence of war and the use of ether had their bearing on the type of subjects discussed. Matters pertaining to surgery and to camp sanitation had a large prominence; while certain other subjects were conspicuously lacking: Thus the great class which we include under the names neurasthenia, neuroses, hysteria, and the various forms of mental disease were rarely mentioned.

Noticeable, too, is the influx of new words —diagnostic and therapeutic— which flood the Records at definite periods, corresponding to the introduction of new members to the society. The resounding terms of dermatology come prominently to the fore with the return of Dr. J. C. White from Europe; and speculation as to the causes of infectious processes becomes rife after the Civil War. Many of our members, more especially Henry J. Bigelow, R. M. Hodges and George H. Gay, bestirred themselves actively as surgical advisers and hospital inspectors at the front, and their published reports are full of interest to us in these days of renewed warfare.

The limits of time and space prohibit my more than referring to the numberless interesting cases and discussions which fill the Records and measure the progress of advancing Science: the early operations on the ovaries; for abdominal abscess; for hernia; the diagnosis and treatment of pelvic disease; operations on the joints; paracentesis; orthopedic surgery; operations on the eye; hygiene; statistical reports; public health— all these, and a hundred kindred matters, occupied earnestly the men of that time, and their discussions developed always more and more on lines with which we are today familiar.

During the past seventy-three years, we have had many domiciles. At first the members met in each others' houses. Then they met in the Washington Street rooms, over Smith and Clark's drug store; then they met in the Tremont Street rooms, over Burnett's (or Metcalf's) shop; then in Temple Place; after the removal of the Medical Library to Boylston Place they followed it there; and now to this distant Fenway.

For the beginning of the third era in the life of the society, I have chosen the year 1868. This was the fortieth anniversary. It marked approximately our first appreciation of aseptic surgery and bacteriological studies. And beginning with this year, there came to join the society a number of those men who now, in their very prime, we recognize as our most conspicuous representatives. It is for this very reason, because this third era is our own era, that one must limit oneself to brief and formal words in dealing with it. Even the naming of names is invidious, except so far as, from time to time, they conspicuously cumber the Records.

However, early in this era, coincident with changes in our personnel, there began one of those declines which every generation has known. The old men ceased to speak; for a time their juniors failed to take their places. And this has always been noticeable to me, that the modest, rising practitioner will surely restrain himself until increase of stored-up knowledge bursts forth to the enlightenment of his fellows. So these men, now our seniors, then young, appear seldom upon our Minutes, and for a space of several years an apparent pause came over our discussions. Yet those were not inactive days. Many men, fresh from the universities of Europe, were developing our laboratories; a new impetus was given to therapeutics and surgical endeavor; Bigelow was perfecting and publishing the two works which especially have made him famous, on the "hip" and "stone"; hospitals were growing; the university was expanding; and new methods of

teaching were absorbing the profession. It seemed almost as if men were too busy to attend meetings so largely clinical as ours. So it came about that in 1880 the society found itself in a condition of semi-decline, and a strenuous effort was made to re-establish it in its ancient vigor. The man of the hour was our distinguished friend and first president, Dr. James C. White. Dr. White had been a member of the society for twenty-one years. He had known well most of its older members. Its objects and traditions and successes were familiar to him, and the authorities therefore resolved to invest him with the office of permanent chairman or president.

Thus, for the first time, the society became possessed of a responsible head. On taking the chair, Dr. White addressed to the meeting a few pithy, statistical words. He reviewed briefly the history of our organization. He showed the work done in former years, as measured by printed pages of Transactions, and the recent work. He called to the attention of members how great had been their influence upon practice, teaching, study and writing; and how deterioration had come with time. Not that work done was less or of poorer quality, but that less eagerly was it given to a listening world. And he enjoined them to reassert themselves, to publish again the results of their labors, and again to push to the fore the position of Boston medicine.

COPY OF DR. J. C. WHITE'S ADDRESS GIVEN IN 1880.

Gentlemen of the Improvement Society: — At your last meeting you honored me with the chairmanship of the society until 1881. Permit me to thank you for it sincerely, and to assure you that I accept the position with full consciousness of the character of its duties. I accept it because I have entire confidence in the success of the plan you have adopted for the improvement of the society, knowing that it is upon your efforts, and not upon my own, that its future depends.

I have thought that the following brief historical data may be of interest at this time.

The society was founded in 1828, and incorporated in 1839. During its first year it had 25 members of whom but 1, I believe, — one still active and honored among us — survives. At the publication of its first catalogue in 1853 the number of members had increased to 60, of whom 3 were honorary and 5 associates. In 1876, the date of our last publication, the regular members had increased to 79.

The immediate roll of the society is: Active members 91, associates 8, total 99; number of new members elected in the last two years, 23.

The first published records of the society appeared in the *American Journal of Medical Sciences* in October, 1848, during the secretaryship of Samuel Parkman, the twelfth in succession in that office. In January, 1855, their publication was transferred to the *Boston Medical and Surgical Journal*, with which it has remained.

		Pages.	Papers.	Pages.
1853, Vol. I.	1848–1853, Transactions,	358		
1856, " II.	1853–1856, "	354		
1859, " III.	1856–1859, "	313	21	202
1862, " IV.	1859–1861, "	258	34	259
1867, " V.	1862–1866, "	242	61	311
1876, " VI.	1866–1874, "	292	25	168
		1817	141	940

The current volume, beginning in 1874, amounts at present to 150 pages of Transactions and 80 pages of paper. The first two volumes contain simply the records of cases presented and the discussions thereon. The subsequent volumes contain not only such extracts from the Records, but in supplement form also the papers read before the society, and published in the *Boston Journal* and elsewhere. The above synopsis of the publications will show the comparative activity of the society in various periods of its existence.

But this society, which bears upon its rolls the names of the most honored physicians of our city within the present century; which has done so much for the advance of pathology and practical medicine, of which its extensive museum and valuable publications are permanent mementoes; the membership of which has been regarded throughout its fifty years as a high honor by the profession, young and old; whose meetings were long so full of interest and instruction — why is it that this society seems about to perish of its own will? Why is it that in the decade, 1856–1866 the Transactions covered 813 pages, papers 116=772 pages? While in the thirteen years which have since elapsed, 1866–1879, Transactions only 442 pages and papers but 318 pages, the publications of the last thirteen years not amounting to one-half of those of the preceding ten years.

Certainly the days of usefulness of such societies have not passed away. In all our large cities, centres of medical learning and seats of instruction, we find them in active and successful operation — nurseries of the most valuable scientific and practical contribution to our literature, arenas of truth-searching discussions. National and international societies, too, of the most important specialties, as well as general in character, have been organized within the last few years, and have contributed greatly to medical improvement, and have excited a good wide interest. All these bodies we find are incentive to the highest professional work, most useful stimulants to progress. In a neighboring city, in a select society like our own, the communications and discussions which characterize its meetings are of the highest excellence in points of originality and research, and exert a wide influence. Why is it that we in this society, its peer in quality of membership we ought to say, occupy a position so far, far behind? Is it indeed, as one of the leading Western journals has recently said, because we really are their inferiors, and in doing almost nothing are doing our best? It is true we are open to the reproach of being a very silent set here in Boston. We are not book makers, and those who know anything of the management of our journal will bear witness how difficult it has always been to obtain anything like a fair proportion even of papers from the local district it represents. But such reticence is only a fashion for which no better reason than influence of descent exists. It can be corrected not only for our own but for the world's good. Boston has, as she has always had, admirable physicians, who have no right to keep their stores of experience and learning locked up in miserly silence; who would find eager listeners anywhere. They are members of this society, and their eminence should not be confined to its consciousness. I am happy to be able to announce that I have met with the most hearty response from all with whom I have spoken of the claims of the society upon their tongues and pens. It signifies the sincere and active interest which still exists in it. It is this which places the success of the new departure beyond a doubt.

Let me state the plan of conduct of the meetings which it is my purpose to observe, if agreeable to you. At present the order of business is strictly fixed in accordance with the printed programme. I desire the liberty of changing this arrangement to suit the character of the communications as they may present themselves, that written or oral communications may take precedence at any time according to their respective importance. It is my intention that two communications shall ordinarily be presented, which shall be announced in the regular notices of the meetings; that these subjects shall be first discussed by one or two members whom I shall especially call upon, and that then they shall be open for general debate. Afterwards the reader will have opportunity of reply. In this way there will always be valuable matter

before the society, and assurance that communications will receive proper attention. Such special discussions will add greatly to the interest of the meetings and to the development of truth. They will be conducted, it need not be said, with that observance of courtesy and mutual consideration which have always characterized the proceedings of this society. It will assist the chairman greatly in the arrangement of business if gentlemen will inform him at the earliest moment of their intention to make communications, or to exhibit specimens of importance, and of course it is not intended that formal papers and discussions shall prevent the freest presentation of incidental communications and general debate. I would suggest, finally, the propriety of changing the hour of meeting hereafter to 7.30 o'clock.

These words were spoken twenty-one years ago. The burst of scientific enthusiasm, the enormous progress in all branches of medical work which have occupied the last two decades here in Boston, tell their own tale.

Unfortunately, perhaps, for the completeness of our Records, much of the best work done in Boston in recent years does not appear in our Transactions. The rise of new societies, local and national, has drawn away from us numbers of epoch-making papers. But many remain to illustrate our annals. Here are a few, hastily gleaned from the Records: In 1873 Dr. Cheever showed how the knee-joint may be opened for a loose body. In 1874 Dr. Thomas Dwight described his well-known method of freezing sections. In 1880 Dr. Hodges read his classical monograph on pilonidal sinus. In this year, also, Dr. Whittemore read a most valuable article on dispensary abuse — the first one published among us. In 1881 Dr. John Homans read his first series of ovariotomies, Dr. James J. Putnam his well-known article on locomotor-ataxia, and Dr. Hodges on railway spine. In this year, also, Dr. Calvin Ellis made his last public communication, "On the significance of albuminuria as a symptom." During these years of the early eighties Dr. Homans constantly addressed the society on the subject of abdominal surgery, and illustrated the feasibility of laparotomy for other than ovarian disease. In 1887 Dr. Ernst's paper on "rabies" is conspicuous. In 1889 Dr. Henry J. Bigelow appeared for the last time before the society to read an account of his identification of the famous Paré portrait. The extremely interesting series of debates on appendicitis began in 1887, and has lasted even to the present time, the early participants being Drs. Fitz, Cabot, Porter, Warren, Gay, Richardson, Homans, Elliot, Watson, and many others. Perhaps the most interesting and conspicuous meeting of the period was that of November 19, 1890, a memorial to Henry J. Bigelow. The profession gathered *en masse* to honor that distinguished man, then recently dead; addresses were made by R. M. Hodges, O. W. Holmes, Henry Lee, D. W. Cheever, Hasket Derby; and letters were read from R. H. Fitz and A. T. Cabot.

Thus we come down to the last event of importance which concerns us as a society — the uniting with the Boston Society for Medical Observation in 1894. Perhaps many of us have already forgotten the existence of that most useful organization. Founded in 1835, by the younger members of the profession, it continued in active, separate existence for almost sixty years; until, finally, its objects, practices and membership became so nearly identical with those of the Improvement Society that it was deemed best to unite the two under the title of the older organization. And we now here represent these two famous institutions.

So much for our story as I read it in our Records. Eighteen manuscript volumes: numberless printed transactions and papers, taken from the *American Journal of the Medical Sciences*, and the *Boston Medical and Surgical Journal*, tell it in exhaustive detail. Its rolls are adorned with famous names. Its purposes have been of the highest. Its vigor has been wonderfully maintained throughout the years. In this society alone is there room for many men of many minds. Here all branches of medical science may be discussed and special research popularized. Here are brought the questions of broadest interest; public hygiene, medical education, medical and surgical advance in diagnosis and treatment, and numerous other matters in which every educated physician should take an active interest.

With such a past, then, and such evidence of present vigor, let us believe that the Improvement Society may impress itself on the future and the coming century.

Original Articles.

NOTES FROM THE NEUROLOGICAL DEPARTMENT OF THE MASSACHUSETTS GENERAL HOSPITAL.

Sudden (Apoplectiform) Bulbar Paralysis; Hemiplegia; Astereognosis.

BY W. E. PAUL, M.D., BOSTON.

Louisa H., fifty-one years old, came to the clinic in Dr. Walton's service. Eleven years ago she was suddenly unable to talk, but in a brief time the disability disappeared, leaving no traces of the attack. A year later, when the patient was forty-one years of age, speech was arrested in the middle of a sentence, she felt dizzy, and the left arm became numb and powerless. Consciousness was retained, vision was not disturbed and there was no vomiting. She could not talk plainly, and was unable to whistle. There was drooling, and on one or two occasions liquids returned through the nose. The left arm continued numb but gradually regained power. At the end of three months she was up and about with some improvement in all her symptoms. At no time have the symptoms grown worse.

Today, ten years after the attack, she talks in a mumbling fashion, unable to enunciate clearly any word in her ordinary speech. She cannot whistle, and she drools on her pillow at night.

There is no regurgitation of liquids through the nose. The left arm feels somewhat numb, dead-like, and the left hand cannot be used in buttoning, lacing shoes, or for the finer manipulations. There is no history of involvement of cranial nerves other than the hypoglossal and facial, nor was any history of impairment of motion of the left leg obtained, though the examination indicated some lessening of sensation of the sole.

Examination.—She was well nourished, ruddy, and clear in mind. There was typical bulbar speech; at rest the lips appeared flaccid; and puckering, compression, and separation of the lips were impossible except in very slight degree. The risorius muscles, the zygomatici, and other muscles supplied by the seventh nerves were normal on both sides. The tongue could be protruded without deviation a little beyond the lower lip, but the tip could not be directed toward the upper teeth or palate. It was impossible to groove the tongue. The palate reflex was normal; and no sensory disturbance could be discovered in the cranial nerves. The left hand could not make fine movements but the grasp seemed as strong as on the right. Tactile sensation was slightly blunted over the hand and fore-arm; at least the answer always was that the horse-hair and wisp of cotton felt plainer on the right. Pain sense (the skin was pinched) was decidedly blunted over the left hand, arm, shoulder and side of the neck, though not lost. The warm and cold test tubes were correctly named each time. Space sense was not lost, but it was impaired, as the points used required wider separation to be recognized as two on the left palm and dorsum; and the answers were less prompt. Pressure sense was altered as metallic substances were called soft. There was preservation of muscle sense, and localization of areas touched was perfect. Objects — a fifty-cent piece, a key, a knife — were unrecognized in the left hand, but were accurately named when in the right hand. The shape of a round tape measure and a fifty-cent coin could not be described, and both were called soft when placed in the left palm. Fibrillation was absent; and atrophy in moderate degree was observed only in the lips and tongue. The knee jerks were normal, there was no ankle clonus, the plantar reflex was absent in both feet, but the stimulation was not felt as plainly on the left sole as the right; the pupils were equal and reacted to light and accommodation. The visual fields were not limited. Nothing abnormal appeared in the examination of the heart and urine. The arteries were not remarkable.

The symptoms of this case, apart from the paresis of the arm, are those of ordinary bulbar paralysis; the peculiarity, on account of which the case is put on record, lies in the mode of onset. The most common type of bulbar palsy is of insidious origin and gradual progression; next in frequency comes the so-called polioencephalitis inferior, which may be acute or subacute, and either come to a standstill or progress; of great rarity are the cases of apoplectiform onset and bilateral lesion in which the palsy may progress or become stationary after more or less improvement. The case reported falls in the last category, and gives no history of change in the bulbar symptoms after the improvement in the first two months of the palsy. The danger of the future, however, lies in the possibility of further degenerative changes, which may begin at any time.

The nerve supply of the orbicularis oris is derived from the facial, but there is good reason to believe the nuclear origin of this supply is from the hypoglossal, either by fibres going to the facial nucleus or entering the facial nerve. "The transverse fibres of the tongue and the orbicularis oris can only contract together."[1] Further, "the orbicularis is always involved in degenerative disease of the hypoglossal nucleus, and escapes in disease of the chief nucleus of the facial."[2]

The labiolingual paralysis in the case reported may perhaps best be interpreted as depending solely on a lesion of the hypoglossal nuclei. It is difficult otherwise to account for the limited facial paralysis.

In the examination the sole of the left foot was much less sensitive to stimulation than the right, an indication that the lower extremity was affected by the original lesion, though no motor loss exists in the leg at the present time. The left arm recovered in large measure from the initial paralysis, but objects are unrecognized when placed in the hand. The existence of hemiplegia and astereognosis are complications of the bulbar palsy difficult to explain in a consideration of the pathology. Gowers[3] states that "These cases of sudden bulbar paralysis, it is probable, depend on softening from vascular occlusion," and adds, "There may be weakness of the limbs or an affection of sensibility, usually in the form of subjective sensations, rarely actual anesthesia." He does not, however, describe a case the parallel of the one under consideration in motor loss and sensory disturbance. It would seem that the lesion extended to the median fillet and pyramidal tract of the right side of the medulla.

INTESTINAL ANASTOMOSIS.

BY CHARLES G. CUMSTON, M.D., BOSTON.

THE question of intestinal anastomosis being a subject of great importance and interest to modern surgeons, it may not be a loss of time to examine the work done in this line by the older surgeons.

In reading a work of great merit, well worthy of the attention of surgeons of the present enlightened times, by the famous Ambroise Bertrandi, entitled "Traité des Operations de Chirurgie," published in Paris in 1769, I was much interested in his really remarkable chapter on hernia.

In it he says, in speaking of the manner of

[1] Gowers' Diseases of the Nervous System, Vol. II, p. 50.
[2] Loc. cit., Vol. II, p. 563.
[3] Diseases of the Nervous System, Vol. II, p. 574.

dealing with gangrenous intestine, that, in the third volume of the "Mémoires de l'Academie Royale de Chirurgie," on page 188, is to be found the following case: "A man, age fifty years, had a gangrenous hernia; it was necessary to resect about two inches of intestine. The surgeon then introduced into the gut a piece of calve's trachea, which had just been dried, then softened in hot alcohol, and then covered with Peruvian balsam. It was provided with five sutures, placed in it at equal distances. The operator then pulled the divided ends of the intestine over it and brought them into contact, and then with two needles he made three points of suture, introduced at a little distance from the edges of the cut bowel. The first of these was inserted on the upper, the second on the under side of the gut, while the third one was placed in the anterior part of the intestine. They were then tied and the gut was dropped back into the abdomen, its walls (of the intestine) supported by the convexity of this piece of calve's trachea, and was abandoned to nature. On the twentieth day a ring of the trachea was found in the feces, and on the fortieth the patient was completely cured." (Literal translation.)

I would here remark that this method of intestinal anastomosis was an old one, even in Bertrandi's day. Pierre d'Argellata speaks of it as follows: "Alii, ut quatuor Magistri ponunt tracheam arteriam alicujus animalis, diende fuunt vulnus, et natura posteà illos expellit canales." I cannot find the names of the four surgeons mentioned in the above quotation, but it is certain that they practiced in Paris at the end of the thirteenth century.

In Chapter XXVI of his work, Fabricius d'Aquapedente also states that some surgeons employ cylinders of elder wood or the trachea of certain animals, but he condemns the use of these materials in intestinal anastomosis.

In the work already mentioned, Bertrandi reports a case of hernia of the appendix, the organ extending into the scrotum, while a portion of the cecum occluded the external inguinal ring.

The Cesarean section, having been of late advocated and performed in cases of placenta previa, it is with much interest that I find in Chapter V of Bertrandi's work the following indications for the performance of this operation, which I will translate: "When the fetus is contained in the womb, and it absolutely cannot make its exit on account of some of the obstacles of which we have already spoken, one should in this case perform the Cesarean operation before the mother and the fetus perish by the violence of the pains, *from hemorrhage*, convulsions, etc."

The first case of operation for extra-uterine pregnancy that I am aware of is to be found reported in Bertrandi's work, and due to a surgeon by the name of Govei: "A young lady of twenty-one years had a tumor in the groin, which was first mistaken for an epiplocele, but arterial pulsations could be made out in it. At the end of two months and a half the tumor had attained the size of a one-pound loaf of bread. Govei opened the tumor on the pressing demand of the patient. He first discovered a kind of membraneous sac, from which a certain amount of quite limpid fluid came away. He dilated the sac and found a male fetus, one-half foot in length and proportionately large. It was living, and was baptized. After having ligated the umbilical cord, the placenta was found attached behind the ring of the muscles of the lower abdomen and to the neighboring parts, but it was separated from these with ease."

Clinical Department.

A CASE OF CESARIAN SECTION.

BY HERBERT J. KEENAN, M. D., BOSTON.

In view of the fact that a number of successful Cesarian sections have been recently done for minor pelves, previa, etc., I deem it my duty, in the interest of statistics on this instructive and useful operation, to report a case done by me some time since.

Mrs. W., thirty-eight years, multipara, was delivered of five dead children. The fifth was the larger one of twins, which preceded the case noted here. Ether, forceps and long lying-in period concluded the above cases, after a tiresome labor of two to four days.

The case was seen shortly after midnight, March 10, 1899, and the following conditions found: Membranes ruptured, os two-thirds dilated, a foot and leg presenting. The anteroposterior diameter was much shortened, owing to a marked projection of the sacral promontory. Pains good, patient's general condition excellent. Considering the previous history, short anteroposterior diameter, and parents' desire to get a living child, a consultation was held with three physicians besides myself to determine the best method of procedure. Three inclined to a Cesarian, one to symphisiotomy. All agreed that it would be impossible to get a live child by dragging it through the shortened diameter. The nature and possible result of a section was explained to the parents, and they consented.

The surroundings were those of the poorer sections of South Boston. An oil lamp on the wall supplied light. The instruments used were those of the ordinary pocket case. The patient was etherized and field of operation made aseptic. An incision was made in the median line; the uterus coming into view, it was next incised in the median line, the membranes torn, the child delivered, the cord tied, and placenta extracted in order. Very little bleeding, only one snap being used. The uterus was then closed with interrupted silk sutures, and replaced; omentum drawn down and abdominal wound closed with silkworm gut sutures. Sterile dressings were applied, and the patient put to bed in good condition. She was given injections of strychnia, brandy and ergotine.

The time of operation was 4.15 A. M. The child and placenta were delivered in a few minutes, less than five; the abdominal wound closed, and the patient in bed in fifty minutes. The child was a girl, eight and a quarter pounds.

The post-operative period was unimportant till the sixth day, when, after a fit of coughing, the wound was opened its entire length, with the escape of intestines. Under chloroform the bowel was replaced, edges of the wound brought together and again closed. Mother and child did well subsequently. Valuable assistance was rendered at the time by Drs. J. B. Lyons, R. N. Daly and J. A. Cronin.

Medical Progress.

RECENT PROGRESS IN THORACIC DISEASES.

BY GEORGE G. SEARS, M.D., AND JOHN W. BARTOL, M.D., BOSTON.

(Concluded from No. 10, p. 237.)

DISEASE OF THE MYOCARDIUM IN CONGENITAL SYPHILIS.[7]

IT is not yet sufficiently well known that congenital syphilis may produce grave vascular disease in children. G. Berghinz records in the *Gazetta degli Ospedale*, of June 24th, 2 interesting cases which throw light on the arterial and vascular lesions which may be produced in infants, and which may result in death in the midst of apparent health. One case is that of an infant eighteen months old, who, while seemingly well, suddenly developed a paroxysmal dyspnea with cough and intense cyanosis, symptoms which possibly pointed to edema of the lungs. There were no symptoms, however, of fever, renal disease, epilepsy, laryngeal spasm, or status thymicus, and the case ended fatally. The post-mortem examination disclosed syphilitic vascular lesions of a characteristic sort (arteriosclerosis) such as occur in the subjects of congenital syphilis, and affecting especially the myocardium. No syphilitic history was ascertained in the parents, but in the second case, in which the same group of symptoms occurred in a child and ended fatally, inquiry revealed an undoubted syphilitic history in the father. Berghinz refers also to an article in the *Centralblatt für Kinderheilkunde* for June, containing a summary of the post-mortem appearances in 22 cases of hereditary syphilis, in which it appeared that syphilis affected the ganglia of the heart and gave rise to a proliferation of the perivascular connective tissue of the blood vessels in the cardiac walls, which eventually resulted in arteriosclerosis and death. It is clear, therefore, that arterial disease due to congenital syphilis, and affecting the coronary arteries and nutrient vessels of the heart, may result in sudden and rapid death, when symptoms of dyspnea and cyanosis supervene in a child otherwise apparently healthy.

[7] The Lancet, August 25, 1900.

It is also interesting to note that many forms of cerebral palsy (hemiplegia and monoplegia) may likewise be the outcome of cerebral arteriosclerosis when the latter occurs in the fetus in utero or in infancy, the results appearing in various forms of paralytic idiocy and imbecility.

PATHOLOGY AND TREATMENT OF ANGINA PECTORIS.

Schott,[8] with a prelude on the pathology in which he supports the well-known "Parry-Stokes" theory, that the stenocardiac crisis "is a sort of syncope, with a preceding strong oppression or pain in or near the heart, the consequence of an organic lesion, the effects of which are brought into evidence by a lowering of the heart power and an accumulation of blood in the cardiac cavities," leads up to a recommendation of the Nauheim treatment for properly selected cases; that is, cases in which arteriosclerosis has not made such progress that the danger of embolism or apoplexy is to be apprehended. Such treatment is more lasting than the usual medicinal one of reducing blood pressure and consequently the work of the heart, because the heart's muscle is strengthened and the cardiac nerves acted upon. The result of his experience has been that "the treatment by baths and exercises has proved to be of signal success, even in cases in which the nitrites, and principally nitro-glycerine, had more or less failed.

DISTURBANCES IN THE BRACHIAL PLEXUS IN ANGINA PECTORIS.

Loewenfeld[9] has studied the relation of the "brachial symptoms" in anginal attacks, and divides disturbances of the plexus into three groups: (1) of sensation; (2) of motility; (3) vasomotor disturbances. (1) The pain (in rare instances extending also to right arm) is distributed chiefly in the regions supplied by the external cutaneous, the greater internal cutaneous, and the ulnar nerves. It varies in degree from slight prickings to the most intense forms; paresthesia is often an accompaniment. He found that in the severe cases pressure on the plexus above the clavicle evoked pain in the region of the heart, as well as in the arm. The same was true of active or passive movements of the arm. (2) The motor disturbances occurred only in severe cases, and consisted in weakness of the entire arm, including shoulder, or in some cases was confined more especially to the forearm. (3) Of vasomotor disturbances in "organic" angina pectoris, he has observed simply coldness and pallor of the left hand in connection with pain.

Brachial symptoms show in different cases quite varying relationship to the cardiac, thus: (1) There may be attacks of stenocardia, even severe ones, in which brachial disturbances are entirely absent. (2) They do, however, occur in most cases, and very often are severe in proportion to the severity of the cardiac symptoms; but not rarely there is a striking disproportion, and either group of symptoms takes the foreground as the

[8] The Lancet, September 8, 1900.
[9] Muench. Med. Woch., August 1, 1900.

case may be. (3) The brachial symptoms may be the first sign of the disease. (4) Pain and weakness of the arm may endure much longer than the heart pang; and in periods *between attacks* light brachial neuralgia may exist by itself, or in connection with slight heart pains.

The theory for the origin of these various manifestations on the part of the brachial nerves is a more or less complicated one. In the ordinary type of case the old theory that the brachial symptoms are due to stimulation passing from the cardiac plexus by the two lower cervical ganglia to the spinal cord, is considered sufficient. Based on Head's localization of the origin of the sensory nerves of the heart in that region of the cord covered by the last two cervical segments and the first eight dorsal segments, corresponding thus to a part of the origin of the brachial plexus, this transfer of neuralgic pains seems not difficult to understand; but for those cases in which the paroxysm is ushered in by the arm pain, or those in which the latter takes the first place in acuteness, it must be further assumed that there exists a hyper-irritability of the centre of origin of the brachial plexus; causes for such hyper-irritability the author thinks he has shown in a reported case of angina pectoris with pre-existing brachial neuralgia, and he also instances the occasional association of valvular disease of the heart with brachial neuralgia as a further proof of the possibility of intimate relationship between heart and plexus. Finally, in such cases as combine the independent existence of both brachial neuralgia and angina pectoris, he concludes that they must react unfavorably on one another.

INTERMITTENT PULSE.

As a result of his experiments, Cushny[10] makes an important differentiation in the varieties of intermittent pulse, and intimates that it is possible and valuable to determine the variety in individual cases. He classifies them as follows: (1) True ventricular intermissions, in which the pause is exactly equal to two pulse intervals, and during which there is no cardiac sound. (2) True auricular intermissions, in which the pause is shorter than two pulse intervals and during which there is no cardiac sound; seen often in healthy persons, and then probably due to excessive inhibition; other cases may be due to auricular disease. (3) False ventricular intermissions, in which the pause is equal to two pulse intervals, but is often interrupted by a slight elevation. In every case a first heart sound can be heard during the intermission. This form appears to be caused by excessive irritability of the ventricle leading to a premature systole. (4) False auricular intermissions, in which the pause is shorter than two pulse intervals. There is often a slight elevation of the pulse during the intermission, and the stethoscope reveals a systolic sound very soon after the last regular pulse elevation. (5) Another variety described by Wenckebach, and not yet studied by Cushny.

[10] British Medical Journal, September 29, 1900.

If the intermissions be of the true variety, some stimulant like caffeine or digitalis would appear to be indicated, while if the intermission is caused by excessive irritability, a drug like aconite acting on inhibitory mechanism might be tried.

SUBCUTANEOUS SALINE INJECTIONS IN PNEUMONIA.

Penrose's[11] statistics as to the favorable effect of the subcutaneous injection of normal salt solution in pneumonia were so favorable that the method was tried by Drs. Ewart and Beaumont in 6 cases under their care. The cases selected were those occurring in unhealthy and debilitated persons, where the disease seemed likely to be severe. The first case was of a severe type in a debilitated female, aged thirty-seven years. One pint of the solution was injected into the subcutaneous tissue of the right subclavian region. Next day the same amount was injected into a similar situation on the left side at 11 A.M., and again at 6 P.M. Altogether there were four such injections alternately on the left and right sides. The patient recovered. The other 5 cases, 1 of which was ordinary pneumonia, 2 double, 1 complicated with empyema, and 1 case of pneumo-typhoid fever, all died. Grey hepatization had appeared in some. The results were disappointing. All but 1 were fatal, but it might be said that the proceeding caused no unfavorable symptoms, and in one or two seemed to have delayed the fatal issue. It did no further good, neither did it promote death. It was not resented by the patients, and the reporters thought it might be given a further trial.

INTRAPLEURAL INJECTIONS OF NITROGEN GAS IN TUBERCULOSIS.

H. P. Loomis[12] speaks of the occasional arrest of a tubercular process in a lung, compressed either by effusion or by a pneumothorax, which from the enforced rest seems to favor a cicatrization of the tuberculous foci. The same effect can be produced artificially by the injection of nitrogen gas, and in the present article he gives his personal experiences with the method. He says that the more he has used it the more he has been tempted to apply it in advanced and hopeless cases, since it relieves the patient and stops many of the distressing symptoms. It cannot, however, always be employed because of the inability to force the gas into the pleural cavity in many cases on account of adhesions, but its impractibility can only be demonstrated by an actual test.

An analysis of his cases shows that the total number in which it was tried was 18, 8 of which were instances of pulmonary hemorrhage which was stopped at once. It was given for its effect on the lungs in 10 cases, in the majority of whom the physical signs remained the same, but pleurisy was controlled at once. Sixteen cases gained in weight on an average of 7½ pounds. None lost. Twenty-nine injections in all were given, the average amount of gas used being 107 cubic centime-

[12] New York Med. Rec., September 29, 1900.

tres. In 13 cases cough improved, 3 slightly and temporarily. The expectoration diminished in 11 cases, and in 4 the fever was lessened. In 8 the injections were tried and failed, owing to the inability to introduce the gas.

He sums up the method as follows:

(1) It is a treatment that has a future; I would advise its more extended use. Only in this way can we ascertain the kinds of cases to which it is best applied.

(2) I have never seen any bad results or even unpleasant effects following the injections.

(3) I have seen no cases result in absolute cure of the disease.

(4) I have certainly seen the apparent arrest of the disease in 2 cases, and the disappearance of such constitutional symptoms as expectoration, fever and cough in a number more. Sufficient time has not yet elapsed to say whether in even the most favorable cases the activity of the disease may not return.

(5) The local improvement is not so apparent as the constitutional.

(6) A marked gain in weight is found in every case injected. This is so universal as to be astonishing, especially as the cases have had no other treatment and many of them have been in hospital wards and under antihygienic surroundings; yet the gain in weight has followed almost immediately after injections, and when a patient had been losing weight before the injections he suddenly began to gain. It is very difficult to explain this effect, except by the marked effect upon the pulmonary lesion.

(7) That this method of treatment will stop pulmonary hemorrhages I am thoroughly convinced. I have never known it to fail, even in one of the most desperate cases upon which it was tried. If these nitrogen-gas injections have no other place in the treatment of pulmonary tuberculosis, it seems to me that their ability to arrest pulmonary hemorrhage gives them a place which no other method we have at the present time can occupy.

THE BRONCHIAL MUSCLES AND ASTHMA.

Aufrecht[13] says that he is in full accord with the majority of authors who accept the theory that asthma is the result of a reflex spasm of the bronchial muscles, but apart from this nervous influence catarrh of the bronchi must also be recognized as a factor in the production of the disease. For the latter no complete explanation has ever been possible. Encouraged by his discovery that longitudinal as well as circular muscle fibers exist in the finer bronchial tubes of rabbits, he has succeeded in showing that a powerful layer of circular and a much weaker layer of longitudinal fibres exist in man. This anatomical fact explains the occurrence of asthma in inflammatory conditions of the bronchial mucous membrane. Here the muscular fibres become edematous, but the function of the circular owing to their greater strength, is less interfered with than the longitudinal, so that a narrowing of the bronchi results, the former being no longer opposed by the latter. In his experience, asthmatic attacks, which result from catarrhal conditions, never become so severe and threatening as those of reflex origin, which is readily explained by the fact that they are not due to spasm, but to an increased contraction of the circular fibre from the absence of their longitudinal antagonists. Owing to the retained secretions and the damming up of the asthma crystals and Curschmann's spirals, bronchial catarrh follows the reflex spasm and may prolong the asthmatic attack for days.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

ARTHUR K. STONE, M. D., SECRETARY.

REGULAR meeting, Monday, January 21, 1901, DR. E. H. BRADFORD in the chair.

DR. BRADFORD: The committee in charge has considered it advisable now that we have entered upon a new era to vary the usual programme of our medical society and look a little to the past. We are beginning a new century, and before laying out our course it seemed wise to examine our chart to take an observation. The committee has, therefore, invited a gentleman to address you, who has not only interested himself very actively in the work of this society the last few years, but one who will also speak to you tonight not in the spirit of a *laudator temporis acti*, but as a historical student telling us the record of the Society for Medical Improvement. I take pleasure in presenting to you Dr. James G. Mumford.

DR. MUMFORD'S subject was

THE STORY OF THE BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.[1]

DR. BRADFORD: As Dr. Mumford has said, the society at one period was in a condition of lethargy, and it was necessary for its good work that it should be revived. At that time the society needed a tonic, and found it in the influence of one who has given new life to this organization. When we read of the names of the past leaders in Boston medicine it sometimes seems to us that the type has changed, but we have in our midst one who, if he had lived in the early part of the 19th century, would have been a leader in the broad field of general medicine. Circumstances channeled his career differently, and you will now be addressed by one who is universally respected as the foremost specialist of America, Dr. James C. White.

DR. WHITE: We have had the pleasure of listening to a full and admirable narration of the past of this society, and yet I may be permitted, Mr. President, in compliance with your complimen-

[1] See page 247 of the Journal.

tary request, to express some opinion with regard to its future, to cast still a brief glance backwards and recall a few personal impressions of its character during my forty years connection with it. Reminiscence, sir, for one of my age is a surer field than prophecy.

When I first joined it in 1859 it might well have been called a small, select and delightful pathological club. Membership was regarded as a high honor, but it was all too exclusive. Three negative votes excluded a candidate, and as personal feelings sometimes found expression through the ballot box, several of the most able physicians of that day, who would have been an honor and strength to it, were denied admission. The meetings were held in the valuable museum of the society, and the seats were arranged around three sides of a large table, which was generally covered by recent pathological specimens. There Dr. J. B. S. Jackson made his inimitable and instructive demonstrations each evening, and although every member present was called upon to make some oral report of cases, they were chiefly those connected with the subsequent exhibition of specimens. Papers on general medical questions were exceptional. Its proceedings at that time were in marked contrast to those of the Medical Observation Society, where clinical medicine was cultivated by younger physicians mostly, in a manner most critical and instructive.

It was truthfully said that the medical profession of Boston of those days lacked ambition. They were content to keep their knowledge to themselves, and to use it for their patients alone, or give expression to it through the restricted circles of these two small societies. They rarely published a book, or lecture, or paper, and thus, with all the varied learning which some of them possessed in eminent degree, they held an inferior position to the physicians of other large cities of the country in the estimation of the medical world. I was for several years, 1863–1866, a co-editor of the *Boston Medical and Surgical Journal*, and remember the great difficulty it had in obtaining original articles from members of the profession here. It was this spirit of reticence or indifference to medical progress through contributions of personal experience which led, I think, to the gradual decline of this society of that epoch. Its brilliant renascence in 1880 was due to the determined efforts of some of its members to rouse the profession from this apathy and force it to give public expression to its long-retained stores of knowledge.

How different it all is now you all know, but how great the change from then only the oldest members can appreciate. Now the books published by our members are numerous and world known. Papers in every department and of the highest merit are most abundant. The papers presented to this society, and the discussions they call forth, are habitually excellent, and deserve the recognition and support of a large audience. This they do not always receive. The average attendance at the meetings, I am told, is about thirty, whilst the membership is two hundred and fifty. How is this general lack of interest in the society to be explained, and how may it be corrected? These are questions which vitally affect its continued existence and future success. In my opinion there can be but one answer to the former. We have far too many medical associations. Permit me to enumerate:

Our Suffolk District Society, in addition to its general sessions, was subdivided a few years ago into eight sections, some of which are in active operation. Then there are the various special societies, namely: The Obstetrical, Gynecological, Ophthalmological, Medical Psychological, Dermatological, the Medical Sciences, the Warren Club, the Thorndike Club, the Clinical Club of Jamaica Plain, of Roxbury, of Dorchester, of the City Hospital, of the Massachusetts General Hospital, also those of towns immediately adjoining Boston, and possibly others I do not know, all in more or less active operation. Besides there are the State and many national societies, general and special, and several international congresses.

Now it is evidently impossible, with all these varied and many interests making constant demands upon thoughts and time, that men can have much of either for any individual society. Some of them must be slighted, and naturally the best thoughts and most time will be at the disposal of that or those in which the individual takes the greatest interest. It is hardly to be expected that any of these associations will obliterate or concentrate themselves for the good of this older and more general society, yet something might be accomplished with advantage in this direction. I have no doubt that an appeal to its members, both old and young, to give it a more earnest and constant support by attendance and voluntary contributions would do much to make its future more assured. I would suggest that but one set paper be presented at any meeting, and that more time be allowed for general discussion and criticism; so that if any member desires to speak upon the subject of the evening he shall not perhaps feel that he is encroaching upon the time allotted for the succeeding paper. Possibly the old custom of assigning an hour for oral presentation of cases or other subjects might be revived with benefit. Finally, I should regret to feel that one meeting a month might come to be regarded as a last resource.

By some such measures as I have thus hastily ventured to suggest, I should hope that the large body of able and energetic young physicians, of which the society may well feel proud, will make of it a vigorous, flourishing and attractive association, devoted to the best interests of clinical and public medicine, which shall long continue to be an honor to the profession of greater Boston.

Dr. Bradford: In listening to Dr. Mumford's account, the thought suggests itself that the great men of the medical past were of different fashion from that of today. The great practitioner of those days was a man of force, who was broad in his range, earnest, energetic, in sympathy with

the spirit of science, a clear reasoner, a keen observer, sound in judgment, and yet often flavored with the grace of the humanities. To find this valued combination of qualities in life and active in vigor we turn to our revered colleague, Dr. Morrill Wyman.

DR. WYMAN: I have very little to say upon the subject suggested. I will say a word or two in regard to a very early matter, and that is the diagnosis of croup. We owe the first clear diagnosis of croup to a governor of Massachusetts, Gov. Dr. John Brooks. In the Revolution he was colonel of a Massachusetts regiment, and led it in the Battle of Saratoga and the capture of General Burgoyne. The war ended, he came home and resumed the practice of medicine in Medford, where my instructor, Dr. William J. Walker, of Charlestown, became his pupil. Dr. Brooks solved one of the first questions of diagnosis when he demonstrated conclusively the presence of a false membrane in the throat in croup. He was able from this to distinguish clearly true membraneous croup from false croup, so called, a disease which in some respects much resembled the other form and the differential diagnosis of which had tested the skill of most practitioners in early medical life; a peculiar "hoarse cold," as it might be called, which is, probably, more closely connected with the nervous system than the mucous, attacking suddenly children in apparently good health after their first sleep at night, producing a more noisy cough, more difficulty in breathing and more alarm, for a short time, than true croup, and yet very seldom proving fatal. Dr. Brooks taught that true croup came on slowly, after two or three days of sickness; difficult breathing was developed suddenly, with a hoarse, peculiar and alarming cough. It was in this form that Dr. Brooks discovered a false membrane in the pharynx which repeated experience proved to him was diagnostic of a very fatal form of croup quite different from the other form with which it had, hitherto, been confounded. This most valuable history Dr. Walker transmitted to his pupils and confirmed its truth by examinations post mortem whenever opportunity offered; in this he was very careful that both the fauces and trachea should be removed and studied. In 1842 Dr. John Ware, in his excellent essay on "The History and Diagnosis of Croup," says, "This circumstance (the false membrane) in the history of croup has been for many years impressed upon my mind by Dr. Walker."

Correct diagnosis brought with it improved treatment — warm applications to the neck and mild narcotics like Dover's Powder, which are uniformly successful in false croup, displacing a needless and sometimes an injurious activity often resorted to under the impression that a fatal disease is impending. I had myself an unexpected result of the application of my knowledge of the distinctive diagnosis I had received from my instructor. I had been, a short time only, a physician in Cambridge, when I was suddenly called to a child with croup coming on after its first sleep. As I had been taught, candle and spoon in hand, I examined the throat carefully, saw there was no false membrane, and complacently told the friends that their child would be better in the morning, and they need not be much alarmed, and gave my directions and prescribed Dover's Powder, saying, as I took my leave, "I will see the child early in the morning." When I called in the morning the door was opened about six inches wide, and I was told that the child was alive; that their doctor had been there all night and had given his *own* medicines steadily. In much alarm I hastened to Dr. Walker and told him I had seen a case where there was no false membrane, and yet the child was dying from croup. He said, "Doctor, the baby will, probably, not die; but I think you were rather unfortunate in telling them so." The patient got well. I was comforted after a time by the opinion of my friends, that of the children I was called to with croup, most were soon relieved — perhaps because they were not first made very sick.

I wish to say that this most important observation in the differential diagnosis of these two diseases we owe to Dr. John Brooks, a president of the Massachusetts Medical Society.

DR. BRADFORD: We have among our ex-presidents one to whom you will all be ready to lend your ears, for he can both tune and charm them — Dr. Clarence J. Blake.

DR. BLAKE: It was a long, low room, brilliantly lighted from near its centre, the confines of the room hidden somewhat in obscurity, not so much so, however, but that there could be seen books upon shelves and the glint of light upon glass cases; a little toward one side of the room a table, covered with a worn cloth of dubious appearance and character unknown, until on closer examination it was found to be broadcloth, apparently, from which the nap had in the course of time been removed, the removal of the nap sometimes carrying portions of the original cloth with it; on this table two or three large metal trays, one of them holding a sponge, another scissors, forceps, knife, a basin, with ewer and towels, a pitcher, presumably filled with water, and two or three glass tumblers; around the table a few horse-hair covered chairs, away from the table and about the walls, wooden seats, chairs and two or three benches. Into such a room there came, with a sense of awe, as if approaching a holy-of-holies, two medical students to whom there had been accorded the high honor of being asked to be present at a meeting of the Boston Society for Medical Improvement. There were but two persons present in the room. One, seated in a chair near the table, was poring over something held between his hands. A seemingly tall, rather gaunt figure, clad in a coat with long coattails; one of the coattails hung down over the edge of the chair and bulged considerably. The bulge of the outline of the coattail did not indicate a round, but a square body. Presently, hearing footsteps on the floor, this man turned his head, showing a rather long, lean face, dark, penetrating

eyes under bushy eyebrows, a somewhat prominent nose, well-defined mouth, the kind of mouth that keeps itself curled up at the corners, reminiscent of the Cupid's bow of childhood. The whole expression of the face turned toward the young man was a most kindly one, its look was accompanied by a welcoming wave of the hand and the words, "Come in and sit down." The other man, standing by the table, leaning over and looking at the object which the other man held, was of shorter stature, and his smiling face, fresh and clear in color, seconded without speaking the welcome to the two medical students, who thus encouraged found their way between the benches and the rows of chairs and took two seats at the back of the room against the glistening portion of the wall which they found to be a series of shelves fronted with glass, and behind this glass numbers of bottles containing preparations, some dried specimens and specimens of bone. Shortly other members of the society filed in and took their places. Simple, friendly greetings, the greetings of men who met every day in their affairs of life, and who now came together with a sense that the day's labor was possibly over, and that here there was to be refreshment for the mind and rest in companionship.

The presiding officer, after calling the meeting to order and going through the business of the day, made the announcement of the papers to be read and communications to be made, and called for them. The first paper was the report of a case; its character I do not remember. The second was the presentation of a second case; then followed the reading of a short paper with its discussion, also short; the third communication included the presentation of a specimen. During the reading of the papers an explanation was found for the presence of the pile of palm-leaf fans which formed a part of the table furniture — palm-leaf fans in the middle of the winter. The tall man whom we had first seen and who had so kindly welcomed us presently reached forward and seizing one of the palm-leaf fans held it over his forehead to shade his eyes from the light which shone downward upon the table. One after another of the members of the society also seized palm-leaf fans to protect their eyes. During the reading of the papers the tall gentleman with the palm-leaf fan was still, but the moment the specimen was brought forward and put upon the table he became instantly eagerly alert. The palm-leaf fan was not abandoned, but simply cocked farther upon the top of his head as he stretched himself forward to catch a clear view of that which was being emptied from a cloth into the platter before him. Then came the reading of the case, a description of the specimen and a discussion of the report, and a demonstration of the specimen, which was passed from hand to hand, followed always sharply and eagerly, as it circulated through the assemblage, by the eyes of the tall man. The specimen came back to the table and the concluding remarks were made by the man who had presented it. He had no more than finished when a hand was put upon his arm: "You don't want that specimen? I thank you." And then we saw the reason for the bulge in the coat-tail, for out there came a square, wide-mouthed bottle; a pair of forceps was drawn from an inside pocket with the speed with which one might draw a stilletto, the specimen was grasped and popped quickly into the bottle and the cover clapped on. With another "Thank you" the tall gentleman retired to a remote part of the room with his prize and the discussion of subjects and the reading of papers went on. The memory picture of that first view of the Improvement Society with the men who made the strength of the profession of that day has remained as an impression of what is best in the medical profession, — skill, training of purpose, intelligence, and immense earnestness. That impression has remained and strengthened through all the years which have followed the acquisition of that very high honor, so esteemed then among the younger medical men, so justly esteemed today, membership in the Boston Society for Medical Improvement.

As the reader who reviewed the society's history has said, the work of this society stands single and alone in many ways, and as one of its presidents has said, other societies have grown up about it and are taking their places in special lines of work. However much other lines of medical activity may be fostered, in the medical community life this society holds a distinctive place. It is preëminently the society through which all that broadly concerns the medical profession as a part of the community whole may most readily be brought before both the profession and the public. It has been, it should continue to be, a rallying point for the consideration of what may be called the sociological obligations of the medical profession, and looking into the future of this society, its past indicates its possibilities in this line of service; it should represent the medical profession as a whole and it should give the medical profession the opportunity to represent itself as a whole in matters of community welfare. Moreover we are coming, in the multiplication of our special societies, to need more and more some one medical organization which shall be a centre for them all. Apparently, with the heritage of its past, to take the initiatory step in the formation of that organization is not only the duty but the great opportunity and privilege of this.

Dr. Bradford: Generations of civilized men have been born, lived and died, and it remained for a member of this society to show that every human being carried inside his abdominal cavity a dynamite cartridge ready to explode. He not only demonstrated this, but indicated the cure. The surgical world owes Dr. Fitz a debt of gratitude for unfolding to it a resource more inexhaustible than the mines of Golconda, but humanity owes him a greater debt, for he has wrested an implement from death.

Dr. R. H. Fitz: Those of us who recall to mind the Medical Improvement Society of thirty years ago realize that a marked and undesirable

change has taken place in its spirit. The society was established for the improvement of its members at a time when medical progress was slow and medical centres were widely separated, if not in distance, certainly in the interchange of ideas. The relatively few members who had enjoyed superior advantages in the acquisition of knowledge and experience were called upon to advise and assist the less fortunate. The meetings were largely attended by the leaders of the profession. Communications of interest and of value frequently were presented and decided importance was attached to the early and complete publication of the proceedings. So much care was taken in the selection of members that those young in the profession generally regarded it as an honor to be enrolled and thus to be brought into more intimate personal relation with those whose example was a constant inspiration. Above all it had an eminent man untiring in his devotion to its interests, the late J. B. S. Jackson, first Professor of Pathological Anatomy in Harvard University.

In the meantime a revolution has taken place in medical progress and a retrocession in the importance of the society. The latter has not occurred without reason and the causes are not concealed. Medical specialization has been the chief means of disturbing the activity and influence of the society, although it should have proved the main source of strength.

As specialty after specialty became represented in the membership a growing number of communications of interest to the few only were presented. Attendance at regular meetings thus was limited to an increasing minority of members subject to constant change in its composition. As the specialists became more numerous special societies were formed and the oculist and aurist, the dermatoligist and neurologist, the gynecologist and obstetrician gradually withdrew in greater or less numbers from active participation in our meetings. The establishment of National Associations of physicians of constantly narrowing interests has resulted frequently in the reservation for these of the best productions of our members even when they were admirably adapted for home use.

The officers of these associations, far in advance of the date of the meeting, have appealed, often with conspicuous success, for contributions from our members and the interest of the meetings of our society has suffered in consequence.

Now we are led to the thought that the Boston Society for Medical Improvement may have outgrown its usefulness and should retire in a dignified manner before evidences of decay become painfully apparent.

We must remember, however, that all physicians are not specialists, that the leaders in medical specialties are those whose training in medicine has been the broadest, and that the ideal association of physicians in communities of sufficient size is that which includes the representative men of each and all departments of medicine. Any association which can bring these together and hold them together always is needed. If this cannot be the function of our society we may rest assured that a society will arise to fill this need. We know that such organizations exist elsewhere and are time-honored. Dr. H. C. Wood, in his remarks prepared for the recent dedication of the new building of the Boston Medical Library, has called attention to the leading functions of the venerable College of Physicians of Philadelphia. He stated that it increased personal friendship and amity, stimulated zeal in study and the acquirement of knowledge, and gave weighty opinions in medical matters of public concern.

Dr. J. R. Chadwick, the librarian of the Boston Medical Library, at the occasion mentioned, suggested that it is for the Medical Library to assume these functions of a medical society and to play the part of the New York Academy of Medicine and of the Philadelphia College of Physicians. He did not, however, give due credit to our society as a source of authority. It is to be remembered that when Boston was threatened with an epidemic of cholera, Mayor O'Brien appointed, on recommendation of Dr. John G. Blake, an advisory committee wholly composed of members of this society — to aid the City Board of Health and to inspire the public with confidence.

It may be that the future of the Medical Improvement Society will bring forth a fusion with the Boston Medical Library since the aspirations of the latter may trench upon the functions of the former. In this event it might be well that a new title should be devised to indicate for each a wider sphere of usefulness than the existing designations suggest.

Were this to result the "Boston Academy of Medicine" might open its library to all but its membership to those only whose association would prove mutually beneficial.

Admitting the necessity of the existence of an organization like our own it is evident that its success must depend upon the general recognition of its functions and a zealous effort to increase its usefulness. As at present its membership must consist of all whose work is earnest and honest and whose example may safely be followed. The wisdom of the elders will be welcome to the juniors whose superior training and enthusiasm will prove a constant source of admiration. To secure such membership subjects rather of general than special interest should be selected for treatment and discussion. Especial effort should be made to obtain the best work of the leading and most active members. Interest in live topics should be stimulated by inviting from elsewhere readers who have distinguished themselves by investigations or experience in matters of novelty or importance. Meetings should be social as well as medical and the largest possible use should be made of the various means of illustration. To carry out these measures the Standing Committee, enlarged if necessary, should hold frequent conferences and should be changed often enough to receive at least one new member in each year.

In conclusion, I would say that the function of

our society now, as heretofore, is to improve the knowledge, power and influence of its members; that its opportunities never have been greater and that it is the duty of us all to avail ourselves of them.

Dr. Bradford: The task of making bricks without straw we know from biblical information is a difficult one. It promoted a rebellion centuries ago, but one gentleman — meeker than Moses, shall we say?— has carried out this task without inciting a revolution. We are not all of us at all times thoroughly satisfied with the brick, but Dr. Shattuck also can complain of the scarcity of the straw. What he has done for our society, what he has done for medical writers in our community, no one knows but himself. The pains he has taken to satisfy the unsatisfied cannot be told. Whatever may be said of our *Boston Medical and Surgical Journal*, it is certainly most independent, most free from servitude to improper influences, and we all know that in the editorial department the *Boston Medical and Surgical Journal* is unsurpassed.

Dr. George B. Shattuck: As I have been sitting here this evening I have been gradually coming to an entirely different view with regard to the piety and character of a Methodist bishop, of whom I lately heard a story which ran somewhat thus: During a period of the late exciting election there was to be a rally somewhere in New York, and the managers had selected some very suitable people to address the meeting, and, among others, they had secured a Methodist bishop who was well known for his eloquence and persuasiveness. The list and order of the speakers had been made out, and his was not the first name on the list, but the first name was that of an eminent lawyer. Before the meeting was called to order the bishop arrived, and immediately on arriving he said to the chairman, "Mr. Chairman, I am to speak first." The chairman said, "No sir. I am sorry, but you are not to speak first. The committee have made out the order of the exercises, and Mr. S., a lawyer, is to speak first. You will speak second." The bishop said, "No, sir. I shall not speak second; I shall speak first." The chairman said, "No; I am very sorry, your reverence, but you will speak second." "Well," said the bishop, "I will either speak first or I won't speak at all." "Well," said the chairman, "then, sir, if you feel that way about the matter, you will have to settle it with Mr. S., the lawyer, who is there, and I will be guided by the decision which you may come to." So the bishop went to the lawyer, and they had it out, and the lawyer said he would speak first and the bishop said that he would speak first; and thus it kept on until the hour for calling the meeting to order arrived, and the chairman said, "Now, gentlemen, have you settled this matter? And which of you is to speak first?" And the bishop said, "I am to speak first." And the lawyer said, "No; I am to speak first." Then the chairman said, "If you cannot settle it, I shall go ahead and follow my list." Then the bishop seized his hat and coat and was about to go out of the room whan his sponsor caught him by the coat and pulled him down into a chair, and the lawyer went on with his speech. By the time he had got to the middle of it a bit of paper was passed to the chairman, who opened it and found it came from the bishop's sponsor and read thus: "For God's sake choke him off. The bishop is playing hell here." (Laughter.) Now, Mr. Chairman, when I heard that story I confess my sympathies were not with the bishop. It seemed that his behavior was marked by impropriety (laughter), but as I have sat here this evening I have gradually come to have rather a keen sympathy with the bishop, and felt that he knew what he was about (laughter).

You were good enough, sir, a little while ago to bid me to come to this meeting — and I always do what you tell me — and you suggested that you desired that I should make a few remarks with regard to the future of this excellent organization. About the day I received this missive from you I happened to dine with Dr. Blake, and after dinner Dr. Blake said, "Are you going to the commemorative meeting of the Medical Improvement Society?" And I said, "Yes. I have got to go. Are you going?" He said, "Yes. I have got to go." "Why have you got to go?" "Well," he said, "I have got to go because I have to speak in regard to the future of the society." "Well," I said, "thunder, but that is just what I am told to do myself. (Laughter.) Now, what I want to know is how big the future of that society is going to be if so many people will have to speak in regard to it." Well, we wrangled over this a little bit, but were not quite as stiff with each other as the bishop and the lawyer, and finally recognizing that I was neither a prophet nor son of a prophet, I said, "All right, you take the future and I will take the *preterit aorist*." So we settled it in that way, and the rest of the dinner passed off amicably, and I went home and spent most of my time after that formulating some remarks in regard to the *preterit aorist* of this society, which I felt much competence to do because although not the son of a prophet I happen to be the son of a former secretary of the society, and I was going on pretty well in that direction when I received a summons from you, Mr. President, by telephone, and you informed me you heard there was the devil and all to pay in the society, that somebody had told you so, because you had asked two gentlemen to speak about the future of this society. "Well," I said, "I have not heard of any real trouble," informing you how it was settled. You said, "Well, you shan't speak about that. You will have to speak about an entirely different subject. What you will have to speak about is the prudential committee of the society." (Laughter.) "Well," I said, "all right. I am much interested in the welfare of the society and having harmony reign here. I will speak about the prudential committee." So I began to think about the prudential committee, and the more I thought about it the more it seemed to me eminently just and meet and right that somebody should say some-

thing about the prudential committee of this society, because it is an extremely important component part of this society, and my impression is that there was a prudential committee long before there was any such thing as a president, and that is another reason why, it seems to me, I ought to have spoken first. (Laughter.) But the prudential committee gets very little recognition. I was in hopes it would receive more recognition in the historical paper we have listened to this evening. If there were no prudential committee there could be no presidents and no secretaries and nothing else. It is really this prudential committee which fecundates the society and prepares the way for the gestation and parturition which eventuate in a president and a secretary. (Laughter.) And really, Mr. President, I think that the prudential committee can regard all these presidents as their children, and a nice little family it is. I have grown gray in the service of the society, working on this prudential committee (laughter), and this is the first occasion when any opportunity has been given for any sort of recognition of the labors of the committee. (Laughter.) Indeed, we teach the president to walk and when his young feet have a tendency to err from the right path we lead them back, and when the secretary is wabbling and demoralized, does not know what to do, and there is no straw, he calls a meeting of the prudential committee and regards it as a practitioner does his hypodermic syringe (laughter) and there is immediately as it were a thirtieth of a grain of strychnia coursing through the veins of the society, and the whole thing is again vivified and reanimated. In various ways, as you indicated, Mr. President, there is much to tell that nobody knows except myself, and I am not going to tell it all. I have told some of it.

I was interested in Dr. White's prognostications with reference to the possible slow decline of this society and how it might be arrested. I was very glad that, although suggesting other measures of arrest, he did not fall back upon that last resort of an inanimate and degenerate society — food and drink and tobacco. That I should consider the last stage of decadence. That is something which is reserved for less zealous and less scientific organizations than ours. (Laughter.) Of course once in a period of seventy-two years it does very well. Seriously speaking, Mr. President, I do think that there is every reason why this society should continue to be vigorous and to grow and to be active and to be useful. As a general rallying ground, as a sort of medical clearing house for all the other societies, whether they be as numerous as now or more numerous or less so, I think that this society will always find an extremely useful place.

DR. BRADFORD: None of us know whether this century is to be an iconoclastic one or not, whether it is to look upon the work of the nineteenth century as an entertaining diversion simply, or whether it is to respect and draw inspiration from the recent past. We have come here into our new home, and you see we have brought with us our Lares and Penates, our family pictures; perhaps it may be interesting to some of you to call up the traditions that these portraits present, or at least to have a suggestion of what can be learned from them. The first is the portrait of an unknown gentleman, not Ambrose Paré, as was once thought, but a Monsieur François Hérard, a bourgeois of Paris. He evidently belonged not to the barber-surgeon but to the surgeon-barber company — to the long-cloaked and not to the short-cloaked surgeons, a mighty difference in those days. The groups contended for centuries, and the contest perpetuated itself and was immortalized by the great Molière, and from the wrangle and the discussion of those centuries came forth the great School of Medicine of France. M. Hérard does not look like a great man, but he must have been a man of leadership in his day, as the picture is an admirable one, and was copied in an engraving to be found today in the Bibliothèque Nationale of Paris.

We next turn to the prehistoric Boston medical past in an admirable portrait of Dr. Danforth, known as Dr. "Danfurth." It is a most excellent portrait by Stuart — our Boston Van Dyck, may we call him? — and tells us of one of whom little is known. Dr. Holmes has said that he was a man whose language frequently resembled the speech of the English army in Flanders. (Laughter.) He had violent prejudices. He contended with the amiable and noted James Jackson, was much respected by his *clientèle* and stands to us as an epitome of dignity and common sense. He is known to have been one of the first to upset the ridiculous practice of excessive bloodletting. He speaks to us of what is gone, with an air of something we would like to have, namely, dignity.

And here is a living portrait of the great surgeon who will stand in the memories of all who knew him, who sat as pupils under him, or who served under him, as a foremost mind. Probably he could marshal more cerebral intellectual force for or against any problem before him than any man of his time in our community. His achievements were great but it always seemed to us, and I think it seemed to him, that they were never up to his rare ability, that he never was pushed to his utmost endeavor. Nor did they equal those of his greater father, but perhaps it was because the circumstances of his life did not bring them out, for his mind and his force and his intellect were peerless.

In the corner is an excellent portrait of what may be called the Genius of this Society — Dr. James B. S. Jackson, the Cruveillier, the Rokitansky, almost the John Hunter and Bichat of Boston. What he did is found in the Warren Museum. What he was has been lost except in the memory of his contemporaries. If he has missed that universal immortality which was his due it is because the community in which he lived were too ignorant to appreciate the wonderfully high quality of his endeavor.

And on the other side is the great master of enthusiasm who brought to medicine the zeal of a

crusader, the fervor of a covenanter, who believed himself, as every practitioner, to be the vicegerent of the Almighty on earth. Of his manifold efforts and of his earnest teaching there remains a monumental work on Consumption and the great impulse which has placed sanitation in our community foremost in the world. We not only could admire his ability, but he was a man who could be loved for his strong human sympathy.

And above him stands the teacher, the gentleman, the scholar, whose interest in medicine began when he sat at the feet of Louis and brought to Boston the teachings of that great school of French medicine. He was the first, I believe,— Dr. Wyman will correct me if I am in error — but I think he was the first to bring to us clearly the difference between typhus and typhoid. His influence has extended to our generation and will live longer, as long as this society clings to the traditions of the past.

And last is the portrait, the excellent portrait, of the young medical scholar who was spared to us too short a time to bring to us the whole influence of his traits. Whatever he did brought with it the scholarship and finish that is an inspiration to every one who knew him. He was the scholar filled with the finish of perfected study.

These pictures may be thought to present to us the spirit that should rule this society's councils; they are the true "genii loci." The work that the society has done, excellent as it has been, should be only the beginning. This society has a place in the community as a focus, the academy, the centre, the place from which should radiate much that is useful in stimulus and in effort towards the best medical thought. This will be its future if the gentlemen who are now members recognize the opportunity and equal it in their endeavor. (Applause.) Motion by Dr. C. J. Blake.

Dr. Bradford: Before adjourning it is but proper that we should pay our tribute of respect to two of the older members of the society who have asked that they should not be requested to speak. Their labors in the society have been so active and so useful that it is but proper that this wish of theirs should be respected. We all of us owe the greatest tribute to the Nestor of the society, Dr. Abbott, and to Dr. Ingalls, whose surgery goes back to the days before antiseptics, and who at the age of eighty performed at the City Hospital, where he has been a surgeon since its establishment, a difficult operation with his usual clear judgment, steady hand, and courteous and careful consideration of his assistants and of his patient.

Dr. Ingalls: Before I received the printed notice of this meeting, I had a courteous and therefore kindly invitation from your secretary, intimating a reminiscent gathering. Fearing I might be called upon to say something, I was about to decline, but I did not; for I thought that as, in accord with nature, I am approaching the vale, I might offer a valedictory. The second half of the 19th century has recently been pretty well sifted by divers writers and speakers; I should like to take you and my friendly audience back almost to the beginning of it, but not quite, however, for thirteen years of it elapsed before I was born; the dedication of this superb building took place on my last birthday. There was a time, within my knowledge, when it was difficult to find subjects for the study and demonstration of human anatomy, and the expedients resorted to for furnishing the imperative necessity required the wit, labor and secrecy of certain Jerry Crunchers. If I relate one or two anecdotes in this line I think an arrest from Chief Wade need not be apprehended at this late day. Between my sixth and eighth years of life these events took place. My father was professor of anatomy in Brown University, and had transferred his lectures to Boston in the uppermost story of Number 30 Market Street, now Cornhill. *Our* house was Number 4 School Street, and the two large rooms of the highest story were devoted, one a dissecting room, the other for preparations; there were several students, among them Sam. G. Howe, Lowell, who afterwards became surgeon-general of the army, Dr. George Capron and Daniel Ingalls. The last named, upon entering the dissecting room one evening, was informed of a "find"; how to get it down to Number 30 was the problem. (*Man crying "Oysters, buy my oysters,"* bag on back. Subject from neighboring town.)

Now I was very friendly with the students and several times they took me down to Number 30 to hear a lecture; and once the lecturer called me from the seat to hold an arm for demonstration; I was the greatest man in the kingdom!

I skip my school days and pass on to 1832, having been one year in Harvard. In 1836 I received my diploma, having studied chiefly under Dr. Charles Harrison Stedman. I must be allowed to recall the names of the professors of my early years; I have ever held them in the highest veneration. Dr. J. C. W. Alway seemed to me to be filled with care; I honored him from a distance; Dr. James Jackson, so kind and gracious to me as to cause me to feel almost on an equality with him; Dr. John Ware, who helped me with some cases, for although I was at that age when I "knew it all" I was always glad of help; I noted his manner with patients, with what gentle forcibleness he drew forth from the sick one everything he desired to know. I learned much from him. Dr. Jacob Bigelow did me the honor to consult with me twice. He caused me to feel as though I was the principal in the consultation, and there were others, learned, skillful gentlemen.

In 1839 I went out to Louisiana, and one of the plantations which fell under my care was owned by Zachary Taylor, in Mississippi, just above the State line. Soon after Christmas time the General called upon me; now, I had two bull-dogs, Vengeance and Fury. I heard a low, short growl, and immediately I sprang through the door and beheld a nice looking elderly gentleman within the gate, looking down upon Vengeance, who had the skirt of his surtout in his teeth, the stranger saying,

"Hi! hi!" — Of course there was sudden release

Returning in 1847, by advice of friends I settled in Winchester, a family doctor, ready for anything under the sun: but I chiefly ran to midwifery, which is now called obstetrics. I have sometimes thought I was born too early; for just think of how one must manage events at the present time, and how adroitly he used to carry himself in those days or nights. For time favored me, for there are even now many grandmothers who were subjects of my helping hand. It seems to me that, generally speaking, neatness is a special characteristic of the profession, and next in importance to the antiseptic.

I would like to speak of my service in the Boston City Hospital from 1870 to 1885, but I have not words warm enough and earnest enough to express my admiration of the character and skill and the friendly Christian bearing of each to all, and, for the most part, the students, in time, seemed to imbibe their modes and bearings from the staff and to do their best. Some of my most ardent and enduring friendships were formed during this service.

Recent Literature.

The Syphilis of Children in Everyday Practice. By GEORGE CARPENTER, M.D. (Lond.), Physician to the Evelina Hospital for Sick Children (Lond). New York: William Wood & Co. 1901.

This little book of 110 pages, 28 cuts, and a short but sufficient index is "based upon a study of several hundred cases of congenital syphilis, met with in private practice and in work at the Evelina Hospital for Sick Children." After a short chapter introducing the subject of congenital syphilis, the next three-quarters of the book is devoted to a consideration of the manifestations of the disease in the different regions and organs of the body, beginning with the skin. There follows a chapter on the clinical history of the disease illustrated by reports of 18 carefully selected cases, and the book ends with two or three pages devoted to "Prognosis" and half a dozen more on the "Treatment" of the disease.

In speaking of the length of time mercurials should be continued, the writer says that he "treats his cases with mercurials for at least a year, and has seen nothing but good accrue from their continuation for two years."

The book presents in a few pages the essential facts of our knowledge of this disease in a practical way and with the author's personal experience as a basis of the work. The illustrations are, many of them, reproductions of sketches made "on the spot" to illustrate the writer's clinical notes of cases, and the book is so simply and attractively written that any student or physician who consults its pages will be tempted to read on, to his further profit.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MARCH 14, 1901

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

TOPOGRAPHY OF THE LATERAL VENTRICLES.

WHATEVER the future of cerebral surgery may prove to be, it is clear that it is desirable that we should have ready and accurate means of determining the relations of various parts of the skull to the surface of the brain, and also to its interior. The relations of the bone to the more important localizing fissures and convolutions have been carefully mapped out, so that, with care and sufficient preliminary measurements, there is small possibility of error. As a matter of fact, a surface growth or hemorrhage is rarely so accurately localized that trephining half an inch one way or the other is a matter of great moment. With the larger skull openings, which may now be made without material added risk to the patient, it is evident that a preliminary error may easily be rectified. There is, however, a very strong possibility that, with increasing accuracy of diagnosis, operations on tumors underlying the cortex may in time be successfully performed. In such cases it will become a matter of growing importance to spare the patient any unnecessary shock, and to this end to cultivate the greatest possible accuracy not only in localizing the position in the brain of the growth, but also to determine with precision the relations of skull and brain. It can hardly be questioned that certain lives might have been spared, and more brilliant operations performed on deep-seated tumors, had we the requisite topographical knowledge.

A further question of cerebral topography which has been curiously neglected is the relations of the lateral ventricles to the surface of the brain and cranium. This has recently been made the subject of an investigation by Edward H. Spitzka of New York, his preliminary paper appearing in the *New York Medical Journal* for February 2d. Tapping the lateral ventricles has

for a period of about twenty years been an accepted if not very frequently performed surgical procedure. It is likely that the operation will be performed more often in the future than in the past, possibly as a ready means of directly reaching the nervous system, as, for example, in the injection of antitetanus serum, or probably more often as a palliative measure in the treatment of extreme degrees of intracranial pressure. In either case, it is extremely essential that the operator should be able quickly and deftly to reach the ventricle through a small cranial opening and with the minimum of risk of injuring various brain structures. An unskilled man may most easily fail entirely to reach the cavity of the ventricle, or he may injure, more or less severely, important structures lying in its immediate neighborhood, like the caudate nucleus or the optic thalamus. Tapping of the ventricle should therefore not be a matter of guess-work, but should be wholly dependent upon an accurate knowledge of the relation of this rather small cavity to the cerebrum and skull. To make this possible is the object of Spitzka's work. Good plates are lacking, with the exception of Fraser's.

In his preliminary work, Spitzka has dissected the heads of two adults. His method of procedure was, in general, as follows: Preliminary arterial injection, skull trephined and lateral ventricles injected with a 10% formaldehyde solution, immersion of entire head in 5% formaldehyde. After one month's hardening the skull was cleansed and drawings and measurements made. Finally the skull was opened and the brain removed, which was carefully measured and drawn. The brain was then cut into sections about a quarter of an inch in thickness. By the aid of tracings and various appliances, the outlines of the ventricles were then projected upon the surface of the cerebrum and skull. The results are figured in a series of excellent diagrams, in which the relations of the ventricles to the brain surface and skull are accurately given. Spitzka points out the fact that a large number of such measurements must be made in persons of varying age and race before a general rule of value may be formulated. There will always be certain sources of error, depending upon individual variations in skull and brain form, as well as upon certain varieties of form and anomalies of the ventricles themselves. Such sources of error may, of course, be minimized by a sufficiently large number of carefully made observations. We hope Spitzka may continue this work, which promises a considerable practical as well as theoretic result. Any investigation which conduces toward the speed and accuracy with which surgical procedures on the brain may be undertaken deserves the warmest encouragement.

IS APPENDICITIS INCREASING?

It is a popular idea, frequently expressed, that certain diseases are increasing in frequency. No doubt the fallacy of such a point of view lies in the fact that as knowledge advances affections once rarely recognized are now easily diagnosticated, with a consequent apparent effect upon statistics. In no condition is this more true than in what we now call appendicitis. The confusion of a few years ago has given place to a remarkable accuracy in the diagnosis and treatment of this disease, and it is therefore quite natural that an appearance of an increasing prevalence should exist. That such is actually the case, however, had not occurred to us before reading certain comments of Dr. Lucas-Championnière given at the last meeting of the French Academy of Medicine, and alluded to in the *Medical Press*. In this surgeon's experience, as shown by an analysis of his own cases, appendicitis is distinctly increasing in frequency. This he believes due to an increase in the sources of intestinal infection, particularly observable in those people, like Americans and English, who eat large amounts of meat. He furthermore thinks that the comparative neglect of more or less frequent free purgation is having a bad effect by permitting the multiplication of organisms of infection in the intestinal tract. If it is true, as has been claimed, that appendicitis occurs more frequently in persons who suffer from habitual constipation, and also in persons given to a meat diet, we may possibly see a means of prophylaxis. Statistics in such a question are of exceedingly questionable value, but whether or not this now so popular disease is actually increasing or not, it appears both reasonable and wise from various points of view to argue that an occasional vigorous cleansing of the intestinal tract is a safe practice to pursue. The meat question is one more difficult to be dogmatic about, but here again no doubt a golden mean is the best policy to adopt. In spite of the fact that appendicitis has been robbed of many of its terrors by the surgeon's skill, it behooves us none the less to be on our guard, particularly when such simple means of prevention may prove efficacious.

MEDICAL NOTES.

University of Pennsylvania Medical Bulletin. — The changes in the *University Medical Magazine*, which were announced in February, appear with the March issue. The title has been changed to read *University of Pennsylvania Medical Bulletin*. The reading matter is printed in double instead of single column, and all advertising matter has been excluded. The

policy and scope of the publication are in no way affected by these changes, since it still continues to be the official organ of the Medical Department of the University of Pennsylvania.

PLAGUE IN SOUTH AFRICA. — Plague continues to spread at Cape Town, South Africa. On March 9th there were 69 patients suffering from the disease in the various hospitals. Europeans are not exempt. At a meeting of the advisory board the government physician is said to have announced that the provisions made by the Town Council for fighting the plague were quite insufficient. Fifteen new cases were reported March 11, and 97 other persons were isolated because of having come in contact with the persons suffering from the affection. The disease is said to be reaching the more prosperous classes.

SMALLPOX IN GLASGOW. — On March 6th, 42 new cases of smallpox were reported, making the total number of patients in hospital 435. This was the worst report up to that date.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, March 13, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 88, scarlatina 31, measles 64, typhoid fever 7.

BOSTON MORTALITY REPORT. — The number of deaths reported to the Board of Health for the week ending March 9th was 238, as against 280 the corresponding week last year, showing a decrease of 42 deaths, and making the death rate for the week 22.14. The deaths from consumption were 22; pneumonia, 39; whooping cough, 2; heart disease, 24; bronchitis, 13; marasmus, 4. There were 3 deaths from violent causes. The number of children who died under one year was 41; under 5 years, 68; of persons more than sixty years, 60; deaths in public institutions, 58.

SCARLET FEVER AT KEENE, NEW HAMPSHIRE. — A somewhat alarming epidemic of scarlet fever is reported from Keene. Some days ago 11 deaths had been announced, with less than 100 cases. The disease has spread to various sections of the city and a number of churches have been closed; the trustees have also voted to close the library building. Rigid quarantine measures are necessary to bring the disease under control.

INTERCOLLEGIATE STRENGTH RECORD AGAIN BROKEN. — A first year student of law at Harvard, Charles G. Herbert, has recently broken all intercollegiate strength records by attaining a maximum of 1,869 points. H. F. Cochems, also of Harvard, previously held the record with 1,809 points. Herbert is said to be a man of small stature, weighing 145 pounds.

DIPHTHERIA IN WALTHAM, MASS. — Diphtheria is reported to have again appeared in Waltham, with 1 death. Some of the cases reported have been sent to the contagious hospital, and the Board of Health is taking precautions to prevent the spread of the disease.

NEW YORK.

AN INCIDENT OF A VACCINATING TOUR. — An amusing incident occurred last week in a large apartment house in the borough of the Bronx, which had been quarantined on account of a case of smallpox. While the inspectors of the Board of Health were making a vaccinating tour of the premises they came across a sneak-thief in one of the flats who, not appalled by the danger of infection, had taken advantage of the confusion of the occasion to slip in and help himself to such valuables as could conveniently be appropriated. He represented, however, that he was "the son of the lady of the house," and, at the request of the inspectors, obligingly offered his arm for vaccination. Soon afterward "the lady of the house" herself appeared, and as she promptly stated that she had no son, the fellow was arrested, when a number of rings and other pieces of jewelry were found in his pockets.

ATTEMPT TO BURN A SMALLPOX HOSPITAL. — On March 9th a mob of about three hundred men, mostly Italians, attempted to burn a small frame isolation hospital in course of construction by the Board of Health at Orange, N. J., and it was necessary to invoke the assistance of the fire and police departments to put out the flames and protect the premises. The hospital is designed for the accommodation of smallpox patients, and there are at present two cases of the disease in the care of the health authorities.

A COMMON AND EXCUSABLE ERROR. — A man was severely injured by being dragged for a considerable distance by a trolley car. On making an examination, the ambulance surgeon of Bellevue Hospital expressed the opinion that because the pupil of the right eye was somewhat more dilated than that of the left, there was concussion of the brain present. "O doctor," said the patient, "you needn't mind the appearance of that eye. It's a glass one."

A LIBRARY BEQUEATHED TO THE ACADEMY OF MEDICINE. — By the will of Dr. Abbott Hodgman, who died in February, his extensive library is bequeathed to the New York Academy of Medicine.

AN AGED JEWESS. — On February 24th there was reported at the Registrar's office, New York

Health Department, the death of Leah Abrams, a Russian Jewess, at the extraordinary age of 114 years.

Miscellany.

APPEAL TO THE MEDICAL PROFESSION OF THE UNITED STATES.

THE undersigned constitute a committee similar to those formed in several European countries for the purpose of receiving subscriptions for a monument commemorative of the distinguished scientific services of Prof. Leopold Ollier. Among the members of these committees are Lord Lister, Professors Von Bergmann, Czerny, Durante and other leading men. The municipality of the city of Lyons has dedicated an open space, adjacent to quarters of the various academic faculties on the border of the Rhone, named in his honor "Place Leopold Ollier."

The profession of this country is well aware of the great services rendered by Professor Ollier, especially in the domain of plastic and osseous surgery. His labors have been most fruitful in the domains of surgery, of physiology and of pathology.

The committee hopes to raise not less than $1,000 as a testimonial from the profession of America. Checks should be forwarded to W. W. Keen, 1729 Chestnut Street, Philadelphia, Pa., at as early a date as possible.

Committee.— Robert Abbe, New York; William T. Bull, New York; P. S. Conner, Cincinnati; A. T. Cabot, Boston; Howard A. Kelley, Baltimore; W. W. Keen, Philadelphia; Rudolph Matas, New Orleans; William J. Mayo, Rochester; W. F. McNutt, San Francisco; Roswell Park, Buffalo; Clayton Parkhill, Denver; Maurice H. Richardson, Boston; Nicholas Senn, Chicago.

RESOLUTIONS ON THE DEATH OF FREDERICK LYMAN THAYER, M. D.

AT a meeting of the staff of the Newton Hospital on March 5, 1901, the following resolutions were unanimously adopted:

WHEREAS, The staff of the Newton Hospital hears with deep regret of the loss of one of its oldest and most honored members by death, and

WHEREAS, The profession of medicine throughout the city loses a valuable associate and wise councillor, and many a poor family will keenly feel his absence when affliction is upon them, therefore it is

Resolved, That in [the death of Dr. Thayer the hospital loses one who, from the opening of the institution, took an active and self-sacrificing part in the practical duties at the bedside. His daily visits were greeted by many who looked to him for sympathy and encouragement. His social and official methods in behalf of the institution will long be remembered and cherished as among the helpful things that have brought it to its present prosperity. By his judgment much that might have embarrassed the government in its developmental workings was avoided.

Resolved, That we extend to his family our heartfelt sympathy, and that we attend the funeral in a body.

Resolved, That a copy of these resolutions be sent to his wife, that they be printed in the city papers and the *Boston Medical and Surgical Journal*, and spread upon the records of the Newton Hospital.

GEORGE L. WEST,
Secretary.

EDWARD P. SCALES, *President.*
FRANCIS E. PORTER,
FRANCIS GEORGE CURTIS,
GEORGE E. MAY,
Committee on Resolutions.

Obituary.

RICHARD J. DUNGLISON, M. D.

DR. RICHARD J. DUNGLISON, a well-known editor and author of many medical works, died last week in Philadelphia. Dr. Dunglison was a son of Professor Robley Dunglison of Jefferson Medical College, Philadelphia, and studied medicine under his father's direction. He was one of the originators of the *Philadelphia Medical Times*, and was the author of "Dunglison's Medical Dictionary," for which alone he will long be held in remembrance, and "Dunglison's History of Medicine." He was in the Federal service from 1862 to 1865, as acting assistant surgeon. He was assistant secretary of the International Medical Congress, 1876, and corresponding secretary of the Centennial Medical Commission, 1876; he was also secretary of the executive committee of the Ninth International Medical Congress at Washington, D. C., September, 1887, and chairman of the finance committee of that congress. Within a few months has appeared the twenty-second edition of his "Dictionary of Medical Science," which stands pre-eminent among books of this sort.

Correspondence.

NOTES ON X-LIGHT: AN UNPUBLISHED METHOD OF DOWERING THE RESISTANCE OF AN X-LIGHT TUBE.

MR. EDITOR:— If the target of an x-light tube is made of sufficient size and thickness it may be used as a reservoir from which gas can be drawn when it is desired to lower the resistance of a tube. In my notes in the *American Journal of Science* I showed that in a properly constructed tube the target must be placed at the real focus of the cathode stream instead of at the centre of curvature of the cathode as recommended by Crookes, Roentgen, E. Thomson and others. When properly placed the surface of the target struck by the cathode stream is an oval spot about two millimetres long. By means of a magnet the point of impact can be shifted to any other part of the face of the target, thus liberating gas from the metal and lowering the resistance of the tube.

Truly yours,

WILLIAM ROLLINS.

METEOROLOGICAL RECORD.

For the week ending March 2d, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Deaths reported 3,044; under five years of age 855; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 629, acute lung diseases 582, consumption 332, diphtheria and croup 88, diarrheal diseases 43, scarlet fever 49, influenza 25, typhoid fever 33, whooping cough 26, cerebro-spinal meningitis 6, measles 13, erysipelas, 15.

From whooping cough, New York, 8, Pittsburg, 5, Baltimore, 2, Philadelphia, 1, Boston, 4, Pittsfield, 2, Springfield, 2, Cambridge and Holyoke, 1 each.

From cerebro-spinal meningitis, Providence, Philadelphia, Boston and Worcester, 1 each, Pittsfield, 2. From scarlet fever, New York, 30, Philadelphia, 9, Pittsburg, 1, Boston, 7, Lowell and Springfield, 1 each. From typhoid fever, New York, 11, Pittsburg, 14, Philadelphia, 5, Providence, 2, Baltimore, 1. No deaths were reported in Massachusetts from typhoid fever.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,789,099 for the week ending February 16th, the death rate was 19.5. Deaths reported 4,408; acute diseases of the respiratory organs, (London) 420, whooping cough 105, diphtheria 71, measles 78, diarrhea, 35, fever, 32, scarlet fever, 27.

The death rates ranged from 11.7 in Burnley, to 28.8 in Liverpool, Birkenhead, 22.7, Birmingham, 22.8, Blackburn, 19.5, Bolton, 16.6, Bradford 13.3, Brighton, 18.8, Bristol, 19.2, Cardiff, 13.9, Croyden, 18.2, Derby, 18.1, Gateshead, 16.7, Hull, 20.6, Leeds, 17.5, London, 19.3, Manchester, 22.5, New Castle-on-Tyne, 19.3, Norwich, 27.3, Oldham, 17.4, Plymouth, 25.1, Portsmouth, 18.8, Salford, 20.1, Swansea, 17.0, West Ham, 15.2, Wolverhampton, 17.9.

SOCIETY NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The Section for Clinical Medicine, Pathology and Hygiene will meet in Sprague Hall, Boston Medical Library Building, Number 8 The Fenway, Wednesday, March 20th, at 8 P. M.

Papers: Dr. H. F. Vickery, "The Plague."

Dr. S. O. Baruch, of New York: "Some Aspects of Hydrotherapy."

Dr. G. C. Smith: "The Value of Suggestion."

Discussion by Drs. J. J. Putnam, Morton Prince and E. W. Taylor.

H. F. HEWES Secretary,
3 Fairfield Street.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the society will be held in Sprague Hall Medical Library Building, on Monday, March 18, at 8.15 P. M.

Papers: Dr. J. L. Goodale, "The Correction of Old Displacements of the Nasal Bones."

Dr. J. S. Stone, "Cleft Palate."

ARTHUR K. STONE, M. D., Secretary,
657 Boylston Street.

EXAMINATIONS FOR DENTAL SURGEONS IN THE UNITED STATES ARMY.

Candidates for appointment as dental surgeons in the United States Army will be examined in the following named branches: Anatomy, physiology, histology, physics, chemistry, metallurgy, dental anatomy and physiology, dental materia medica and therapeutics, dental pathology and bacteriology, orthodontia, oral surgery, operative dentistry, theoretical; prosthetic dentistry, theoretical; operative dentistry, practical: prosthetic dentistry, practical. An average of 75 per cent. will be required in each subject for theoretical examination, and 85 per cent. in the practical examinations.

RECENT DEATH.

ROBERT STONE, M. D., of New York, sixty-four years old, died on March 7th, after a tracheotomy operation for an affection of the throat. He came of an old Massachusetts family, and was the son of Joel Stone, a prominent New York merchant. He first attended lectures at the Yale Medical School and was afterward graduated from the College of Physicians and Surgeons, New York. In 1864 he was appointed an assistant surgeon in the United States Navy. A considerable portion of his professional career was spent in Yonkers-on-the-Hudson.

PUERPERAL INSANITY.[1]

BY ARTHUR C. JELLY, M. D., BOSTON.

The so-called puerperal insanity is not common, and without doubt some of you have never seen a case of it; but those who have been so unfortunate as to have such cases occur in their practice will probably agree with an eminent alienist, who characterizes it thus: "I do not know of any event that can occur in a family, short of death, that is so great a shock to all who have to do with it as for a new-made mother of the first-born child to become suddenly maniacal and require to be sent to an asylum. One of the most joyous times of life is made full of fearful anxiety, and the strongest affection on earth is then often suddenly converted by disease into an antipathy." Certain specialists believe that preventive measures might sometimes have been made effective, if the attending physician had appreciated the earliest symptoms of impending danger. The gravity of the condition and the possibility of prevention appear sufficient reasons for presenting the subject before this society.

In examining the medical records of the Institutions' Registration Department of the city, with reference to the question of the increase of insanity, I was struck with the apparent decrease of puerperal insanity, though certain names of women afflicted with this disorder were frequently encountered. Without expecting to add very materially to the present knowledge of the subject, I wondered whether it might not be worth while to collect all the cases where the puerperal state was the assigned cause of the mental disorder, and then to ascertain their hospital record, and possibly their subsequent history. Such a collection might give a broader view than was afforded by the records of any one hospital.

From 1872 to 1900 about 250 such patients were examined. Fifty of these have been excluded, because the conditions found did not warrant a certificate of insanity, or because a rapid improvement, or some other reason, led to keeping the patient at home, or because the insanity was due to other causes than the puerperal condition. There remain about 200 where the puerperal state is the alleged cause, whose hospital record is at our disposal. These people represent the middle and lower classes socially, some very poor, others in comfortable circumstances. The majority were examined at home; some in hospitals or charitable institutions; others in the hands of the police at the House of Detention; 12 had been recently delivered at the Lying-in Hospital.

The term "puerperal insanity" may be used broadly to cover cases of disorder arising at any time during pregnancy, or soon after confinement, or several months later; but it is customary to limit it to cases which develop within six weeks after delivery, and to describe the other cases by the terms "insanity of pregnancy" and "lactational insanity."

In the early months of pregnancy, it is not so very uncommon to encounter symptoms of mild mental disturbance, such as irritability, eccentricity, perverseness, moderate depression of spirits. Such a condition usually lasts only a short time. If the disorder appears for the first time toward the end of pregnancy, it is apt to be much more serious in character and longer in duration. Sometimes a slight improvement may be noted after delivery, but it is usually only temporary, and the patient soon becomes worse. Thus it is evident that delivery has not essentially improved the mental condition. On the contrary, a mild case frequently develops in the week following delivery into a very severe one.

The insanity of lactation seems due largely to anemia and debility; its symptoms are usually gradual in onset, subacute in course, not very grave in character; on the contrary, some cases show a sudden onset of violent excitement with fatal termination, and others profound melancholia with suicidal tendencies.

It does not seem consistent with the laws of nature that a normal woman should become insane from passing through a physiological process. And yet this process brings such great changes, physical and mental, that one's neighbor is shocked rather than surprised upon hearing that an attack of insanity has quickly followed childbirth.

From an etiological standpoint one may divide cases into two distinct groups: In the first, the puerperal conditions appear to be the sole cause of the insanity; such are those due to sepsis, many due to exhaustion, some probably due to auto-intoxications. In the second group, preparations were already made, and the puerperal state opened the door, and thus the psychosis was liberated (*ausgelöst*—Kraepelin). In other words, it acted here just as worry, financial losses, grief or the period of puberty may act to add the weight needed to turn the scale. Indeed, there may occur several attacks of this sort in the same person, where each attack was apparently excited by a different one of this group of causes.

Another group should be mentioned. A defective or somewhat demented person, or one who has delusions (though living comfortably and quietly under the conditions of ordinary domestic life), may, when pregnant, become excited or depressed, and present a picture whose most striking features may be those of a puerperal insanity, but in which features of the chronic state are detected upon critical examination.

If, now, we turn to the clinical features and ask whether there is anything that we may describe as a type of puerperal insanity, we find just such a diversity as would naturally be expected from what has just been said. Viewed rather superficially, many of the clinical pictures do not seem to differ very much one from another, but on closer inspection may show widely differ-

[1] Read before the Obstetrical Society, May 15, 1900, and unavoidably delayed in publication.

ent diseased states. The following cases will illustrate this point: Of 3 cases, where the striking feature was a perplexity, due apparently to confusion, with restlessness, insomnia and anorexia, the first was an attack of simple excitement, the second was upon a basis of congenital defect, and the last was an episode in the course of a general paralysis. Three cases that would impress one at once as melancholia, proved on analysis in the same way to represent: one an attack engrafted on a slight congenital defect, another a form of recurrent psychosis, the third a general paralysis. Thus it seems best not to attempt the description of a sort of case which seems most typical, but to bear in mind the possibility of wide differences — important especially for prognosis.

Insanity is said to occur once in 400 deliveries. As to its frequency in hospitals for the insane, the following figures may be quoted:

	Puerperal.	Pregnancy.	Lactational.	Total.
Clouston,	5%	1%	4%	10%
Krafft-Ebing,	9.2%	5.6%	3.1%	17.9%
Kraepelin,	6.8%	9%	4.9%	14.7%

Our ratio is 3 puerperal and 2 lactational to 1 of pregnancy.

Etiology. — The relation between etiology and prophylaxis is so close that we are warranted in studying the causes in detail. The great predisposing cause of insanity in general is heredity. We should look for this in the collateral as well as in the direct lines of the family, and we must consider epilepsy, apoplexy and various nervous diseases, because these may lead to nervous instability of such a sort that the person is liable to serious breakdown at any period of stress. A history of heredity is found in about one-third of our cases. This undoubtedly does not represent the whole number, because such a family history is often concealed.

Tuberculosis is so often found in the family history of cases of insanity that it must be admitted to be an important predisposing cause.

Alcoholism is an important factor, because if it exists to any great extent in either parent of the woman, it may lead to those neurotic conditions in her which predispose to insanity. Moreover, a woman may, by drinking to excess, be laying the foundation for an attack of insanity when she becomes pregnant. It happens, however, sometimes that the alcoholism is merely one of the signs of disturbed mental condition due to pregnancy in a woman temperate when not pregnant.

Epilepsy or even profound hysteria may possibly be responsible, according to Kraepelin, for certain sudden outwardly severe delirious states of excitement, which arise rarely during the act of delivery and soon pass off. In certain of our cases epileptics during pregnancy or after confinement developed insanity.

The physical condition seems often the only important etiological factor. As psychic causes, grief, fright, worry, domestic unhappiness are mentioned frequently. In such instances as the following, worry might easily play an important rôle: A woman had an attack of insanity after each of her three pregnancies, and her sister, a primipara, could not banish from her mind the probability in her own case; a woman whose mother had died in childbirth learned when seven months pregnant of the death of her sister from puerperal fever. In such cases there may be no history of hereditary tendency. Undoubtedly, illegitimacy operates as an important psychic factor, though the poor physical condition often associated with illegitimacy must not be overlooked. Clouston states that insanity is twice as common after the birth of illegitimate as legitimate children; and this is exactly the ratio in the Lying-In Hospital series — 8 of the 12 were single women.

How many cases are clearly septic? This is the most important division of the subject for you. Dr. Chapin attributes the decrease from 99 very acute cases admitted to the Philadelphia Hospital in the ten years preceding 1877, to 20 such cases in the ten years preceding 1897 to the introduction of stricter antiseptic measures in obstetrical practice in Philadelphia; and he emphasizes the opinion that a further reduction might be made if in every case every source of septic infection could be excluded. Dr. Brush, in the *American Medical Quarterly*, cites statistics from the Kalamazoo Asylum, where the percentage of puerperal cases fell from 7.8% in the decade 1877 to 1886, to 3.8% in the years 1887 to 1896, and also from the asylum at St. Peter, Minn., where the experience was similar. In Boston there has been a decrease in ratio, puerperal to total female cases as follows: 1872–1880, 6.4%; 1880–1890, 4.6%; 1890–1900, 3.7%. But an examination of the most acute cases, some of which were clearly septic, fails to show a corresponding decrease. It seems fair to assume, therefore, that here in Boston prevention of sepsis has played a less important part than some other factors in the reduction. In this connection it has been suggested that a state of the pelvic organs resulting from previous disease may be the starting point for a septic process in spite of perfect technique on the part of the obstetrician. It is certainly a fact that certain cases of excitement which have been attributed to profound exhaustion are clinically like septic cases, except that the temperature is usually not so high, and there is no vaginal discharge. Possibly an ether examination would help somewhat.

In spite of our rather favorable statistics, however, this subject is so important that we may expect our profession to continue improving its methods until no case of insanity can be justly ascribed to puerperal sepsis.

Toxic States. — Defective elimination by the kidneys leads to delirious states which are frequently very transitory. The following extract from Kraepelin loses something in my imperfect translation: "The psychic phenomena of poisoning depend, (1) on the kind of poison; (2) on the rapidity with which it does its work. Rapid poisonings of the brain are usually expressed in conditions of delirious confusion with more or

less lively disturbances of sense-perceptions and often with excitement. While in slow destruction by the poison, signs of intellectual paralysis occupy the foreground. Naturally in each case the clinical picture is determined very essentially by the special properties of the poison. From the work of Nissl and others it seems probable that for every poison there is a characteristic disease-process in the nervous tissue, whose special traits we may learn to separate, in the earliest stages, even anatomically. Moreover, the investigations of the psychic effects of poisons — as far as they have been exactly carried out — have taught us that for every poison there is a special distribution of effect upon the different regions of the soul's life. Likewise, we are at last in a position to recognize in many cases the nature of the poisoning by the symptoms observed clinically. Only in rare forms, in most of the auto-intoxications, in many slow and insidious poisonings, is it still impossible to infer the cause of the disorder from the clinical picture."

By analogy it seems probable that when careful clinical observations and accurate laboratory studies are made simultaneously upon the same cases, we may find a sort of puerperal insanity due to auto-intoxication. Such a group might include many cases now attributed to exhaustion.

Sometimes several causes appear to have played a part in producing the disorder. This record made in one case under supposed cause shows the thoroughness of one physician: congenital mental deficiency, alcoholism, masturbation, confinement, and grief at loss of child. But sometimes no cause is found except the puerperal state itself. Indeed, Clouston says, "In far the majority there is no other exciting cause; the psychology of pregnancy has not been written." There are certain individuals whose makeup is such that they are liable to serious mental disturbances when the stress of their environment becomes great. Such women naturally have trouble at puberty, at the climacterium and in the puerperal state.

Symptoms. — In many cases symptoms were sudden in onset and severe in character, and reached a climax of wild excitement in twenty-four hours. Frequently, however, symptoms mild at first gradually increased in severity or suddenly gave way to an outburst of excitement. In cases of gradual onset the first symptoms noted were frequently these: A change of manner so that the patient became somewhat indifferent and neglectful of the child and of her household duties. She grew reticent, and her face showed a peculiar expression of watchfulness, as if she were anxious and yet unwilling to reveal her state of mind. On the other hand, many patients were moving constantly, talking incessantly, as if somewhat exhilarated. Nearly all showed early loss of appetite and inability to sleep. Later a patient may be confused, suspicious, resistive, depressed, less often excited; frequently she has impulses to suicide, or she makes attempts at suicide in an impulsive way; less often impulses or attempts to injure the child are recorded. Assaults upon others are usually due to fear. Rarely there is a condition of marked stupor. Seldom does a patient become exhilarated in the strict sense of the word, that is to say, with a marked sense of well-being, rapid flow of ideas, and extreme activity, with a thoroughly happy state of mind. On the contrary, in our cases, though they were frequently noisy and incoherent and very active, and sometimes destructive and violent, these symptoms appeared to represent a mental state of confusion or perplexity, with a feeling of helplessness. Wernicke's term "Rathlosigkeit" is most aptly applied here. Hallucinations occur, of hearing more often than of sight, and they are usually of a distressing character. Delusions are also distressing and frequently are concerned with religion.

Course and Outcome. — After a short period many of the most excited cases become comparatively quiet and no longer suffer from hallucinations and delusions. Sometimes this change is so rapid that a diagnosis of alcoholic insanity is made; and in certain cases this factor is undoubtedly partly or wholly responsible for the condition. But if the case were due to an auto-intoxication, which ceased under the conditions subsequently established, then we might reasonably expect an equally rapid subsidence of symptoms.

English writers especially emphasize the short duration and curability of this group of cases. Clouston writes that 75% of his puerperal cases recovered completely, while 8% died; that 90% of these recoveries took place in six months; that 77% of his lactational cases recovered, 80% of them in six months; that 60% of the insanity of pregnancy recovered. Krafft-Ebing gives the average duration of hospital cases due to pregnancy and lactation as nine months, and eight months for puerperal cases. Many septic cases are of short duration and end in death. Others improve after removal of the source of sepsis, but not all of them recover.

Some cases of exhaustion live only a few days. If they recover, more time is needed than for the septic cases as a rule.

Many cases of excitement, on the road to recovery, pass into a state where they are more quiet than is natural for them when well, or even into a condition of stupor. And many others who do not appear especially dull have no subsequent recollection of the events of the attack. Some have exacerbations of excitement, followed each time by an improvement until recovery is established. The average case improves gradually, often the body before the mind, but usually both together.

Recurrence. — Thirty patients had more than one attack. In 6 all the attacks were puerperal (including here pregnancy and lactational). In 8 the first attack was puerperal. In 5 the first attack was not puerperal. In 11 the first attack is not accurately described, later some attacks were puerperal. In many the attacks were very similar in symptoms, course, duration and outcome, others showed considerable variation, but

are to be regarded as representing similar disease-processes and clinical pictures so much alike that they may be classed together. One woman was admitted to a hospital for the insane in 1870 in her first attack and in 1899 in her seventeenth attack. She has been discharged, recovered or much improved, seventeen times and is said to be very little if at all demented.

ONLY ONE ATTACK; 147 PATIENTS.

	Total.	Recovered.	Died, Acute.	Died, Chronic.	Living, Chronic.	Result in Doubt.	Average Duration—(including hospital residence and duration previous to this).
Puerperal, very acute[1] cases.	47	36	4		7		36 cases, 7.0 mos. 34 " 5.5 "
Puerperal, less acute[2] cases.	31	11	2	4	13	1	11 " 6.5 " 10 " 5.8 "
Lactational cases.	46	14	3	5	19	5	12 " 7.5 " 10 " 6.0 "

Dementia Precox.	3	1		2		
Delusional Insanity.	5	2		1	2	
	20	5	3	6	5	1

In calling your attention to the figures that follow I feel bound to express my skepticism as to the value of statistics of this sort. No matter how carefully compiled, they are necessarily inaccurate. Allowing for this inaccuracy, however, they may be useful if considered very broadly.

Prognosis. — The prognosis as to life is very good. Of our cases 13 died in the first attack and 3 in the second; of the chronic cases, 14.

The prognosis for recovery from the attack is variously stated to be from 70% to 80% of the cases in asylums, and since many mild cases never go to an asylum, the percentage of recoveries is often stated as probably nearer 90%. Our cases do not warrant so favorable a prognosis. Moreover the tendency to recurrence must be taken into account, because, as we have seen, many cases recover from several attacks, but finally become chronic and demented.

The insanity of pregnancy does not disappear with delivery. A short temporary improvement should not mislead us, because often the patient soon becomes worse than ever before. Speaking of insanity in general, Clouston says, "I look upon a temperature of 100 and over with alarm in any form of mental disease, and in the estimation of the intensity of brain overaction, one-half a degree is equivalent to two degrees in the measurement of a febrile disturbance."

The return of menstruation is a good sign, not because it in any way leads to recovery, but because it indicates a return to normal condition on the part of the bodily functions. Recovery once well started usually progresses steadily, so that patients are frequently allowed to leave the hospital much earlier than when they are suffering from any other form of mental disease.

We have seen that the same clinical picture may have for its foundation a very different diseased state, and, therefore, before giving a prognosis we should be careful to determine whether we are dealing with a simple or complicated condition; because, after all, "The prognosis will be dependent upon the degree of defect in the nervous organization of the woman rather than any external conditions which may have complicated what might have been otherwise a physiological process."

Treatment. — At the outset it was suggested that possibly some of these cases might be prevented if the physician has in mind the conditions which are liable to lead to attacks of this sort, and if he is alert to note the early symptoms as they appear. It seems hardly possible to emphasize too strongly the importance of prevention, for though the mental symptoms of pregnancy are usually mild and temporary, and frequently pass off without treatment, this is not a sufficient reason for neglecting to treat the patient seriously, because, as we have seen, many cases pass gradually into a very serious condition, which leads to an attack of insanity, and ends in dementia. When the physician has reason to suspect the existence of conditions favorable to the development of insanity, he should instruct the patient to establish the most perfect hygiene possible in her home during her pregnancy, and if danger

signals, pointing to instability, appear at any time, he should at once seek to remove the cause if possible, and endeavor in every suitable way to restore the balance. Special attention should be paid to the digestive and eliminative functions, to exercise in the open air; excitement should be avoided, and sources of annoyance removed. Sleep is very important. If the conditions just mentioned are fulfilled, especially if the person is much in the open air, sleep may sometimes be obtained without the use of drugs; and we should avoid drugs, not only on general principles but out of consideration for the possible effect upon the child. Serious mental disturbance during the pregnancy is not to be regarded as an indication for inducing labor.

When mental disturbance appears after delivery it is wise not to act hastily, but to wait until it is clear that the patient is suffering from something more than a mere temporary affair before deciding the question whether she shall remain at home or be sent away for treatment. Since many cases which are explosive in their onset, and which show the gravest symptoms, are very frequently of short duration and end in recovery, it is often desirable that such should be treated at home if possible. Moreover, septic cases require surgical treatment of local conditions and such general treatment as would be proper for a septic case with fever and delirium, so that even violently maniacal cases of this sort may be treated at home if a sufficient nursing force can be obtained. In cases of profound septis or rapidly progressive exhaustion, death is liable to occur within a few days, and it is especially unfortunate to remove such a patient to an insane hospital and have her die there in twenty-four hours, as happened in one of our cases. Moreover, one may question whether the journey to the hospital might not be enough to turn the scale; therefore, one may properly hesitate about sending such cases away. If home treatment is adopted it frequently is necessary to turn a portion of the house into a hospital, because the patient may become excited, noisy, violent, destructive, suicidal or homicidal. Our first consideration must be to prevent loss of life. The presence of the child, and in less degree also of the husband, appears often to be a source of nervous excitement and irritation to the wife, even when there is no real danger from impulsive acts on her part; but a sufficient number of cases have been recorded where the mother tries to kill the child to warrant us in saying that it is usually desirable and frequently necessary to separate the mother and child because of danger to the latter.

Our next care should be for the mother herself. The physician should explain to every one in attendance how great is the danger of suicide, how stealthily and suddenly and rapidly such people often commit the act, and he should demand the greatest vigilance on the part of every one. Moreover, this caution should be given not only at the outset, but should be repeated at frequent intervals afterward, because if the patient improves the attendant may omit precautions too soon. The next indications are to maintain strength, to improve nutrition, and to insure sleep. Cases of mania frequently take food readily, so that we have no great difficulty in providing sufficient nourishment to meet the vast demands upon their strength, made by their great activity; but the majority of puerperal cases suffer from a loss of appetite which may be so great that they refuse all food. No time should be lost, but vigorous treatment should be begun at once by the use of simple, easily digested nourishment at frequent intervals. Nutrient enemata may be of service, but usually feeding with the tube, through the mouth or nose, will be necessary in the severe cases. This is neither easy nor safe in the case of an excited patient without the help of several assistants. It is often wise to peptonize some at least of the food so given.

It is usually necessary to give more or less alcohol. Insomnia is a sympton which calls for attention very early in the majority of cases. Sleep of several hours' duration will often follow the administration of food and stimulants, but hypnotics should be used freely at this time if necessary. There can be no doubt that here, as in an impending attack of delirium tremens, a few hours' sleep may prevent a serious and prolonged attack. After giving a reasonable quantity of the hypnotic selected, if the patient remains wakeful more food and stimulants should be administered, when it is often almost wonderful how soon sleep comes. If the patient wakes early in the morning hot milk or broth should be made ready promptly and given at once.

Puerperal cases in the excited stage are so oblivious of the calls of nature that the bladder may become over-distended and the rectum overloaded. Moreover, such patients are more or less anesthetic, so that they do not complain of pain or discomfort as ordinary patients do, and thus your attention will not be called to the condition of these organs or to inflammatory trouble in the pelvis or elsewhere.

In the treatment of lactational cases it is of course naturally suggested that nursing should be stopped and that debility and anemia should receive proper treatment. A large number of these cases are depressed, and in many the depression is profound and there is a tendency to suicide, which is attended with greater deliberation and is carried out less impulsively and therefore with greater chance of success than in the puerperal cases; so that it is necessary to guard what often seems a mild case from this danger.

Home treatment of insanity is possible for only a few cases. The expense is too great for most people, and the private or public hospital is a necessity for all such.

THE GRAVE OF HIPPOCRATES.—A London paper reports, according to the *Medical News*, that a telegram from Athens announces the discovery of the grave of Hippocrates, during excavations at Larissa. The report needs verification.

MEAT RATION IN THE TROPICS.[1]

BY P. R. EGAN,
Surgeon U. S. Army.

FOLLOWING the late Spanish War, American soldiers were scattered from the Arctic Circle to the Equator. Speculation as to their requirements under these new surroundings soon became rife. The necessary clothing alterations were sufficiently apparent, but the requisite food is still a matter of discussion. In the first days of the occupation of Puerto Rico an officer of the line wrote home that his principal food consisted of crackers and milk, and that he was in excellent health because he avoided all heating diet.

Physiologists had for a long time observed that there was a rise of body temperature of nearly one degree in the tropics; that the pulse rate was lowered; that respiration and blood pressure were diminished; and that there was a marked languor and tendency to depression. Proteids and fats increased heat production, and should, it was stated, be abandoned or used very sparingly. They also proceeded to analyze the diet consumed by the Negro in the Antilles, the Hindoo in India, and the Malay in the Eastern Archipelago, and to point out a great diminution of the proteids and fats in his dietary. But they also discovered that the carbohydrates were diminished to an equal degree; or, in other words, that their diets were those of chronic starvation, a condition that exists to some extent in most tropical countries where the rate of increase of population is so great that the country is unable to raise sufficient produce to feed them, and where, as in India, famines are now beginning to be regarded as inevitable. Overlooking these facts they declared that there was need of more sugar and tropical vegetables, and less meat and fat to reduce our dietary to their standard; that is, to the standard of those who are unable to procure nourishing food. But coming nearer home, these same physiologists would not for a moment declare that because the Crofter lives on oatcake, and the Cottier on potatoes, that the diet suitable to Scotland was oatmeal, and to Ireland potatoes. Yet, guided by their theories, some, like the line officer, lived principally on crackers and milk, and others believed like Major Louis Livingston Seaman, surgeon to the First Volunteer Engineers, who is reported as declaring before the board of officers on the Tropical Ration that what should have been a delightful outing for his regiment was turned into a tragedy because of the heating foods his troops had to eat. When they landed in Puerto Rico not a man was on sick report. In less than three months nearly one-third of the regiment was on the sick list, and the rest were scarcely able to carry their personal belongings when they reached New York. Dr. Seaman said that all had suffered from bowel irritation, and that when they needed delicate food they had to use that which had inflamed the intestinal tract and had produced symptoms like a catarrhal condition, making the patient peculiarly subject to attacks of typhoid and other fevers. He also said the food used was diet food and not the regular rations. However, few of the persons who have had extended experience of the Tropics agree to the so-called heating effects of the proteids; nor does the diet of the natives who can afford other than starvation fare tend to support this theory. The late governor, General Henry, of Puerto Rico, wrote in December 1899: "The better class live and dress like ourselves. The food of this class, is for the early meal, coffee and bread for breakfast; at noon, coffee, vegetables, eggs, meat and dulces, or sweets. The night meal is about the same. They are great meat eaters, it being cooked in various ways."

In January of the same year Colonel O'Reilly, chief surgeon, Division of Cuba, who had been sent to Jamaica to investigate how Great Britain cares for her soldiers in the tropics, reported: "No improvement on the present ration of the United States can be suggested. If it errs at all it errs on the side of too great liberality." In December, 1899, I wrote the following letter to the *Boston Medical and Surgical Journal*: "As a supplement to the article of my scientific friend, Colonel Smart, on the "Army Ration," let me add a few practical observations gathered in Puerto Rico. Duty has taken me at one time or another, since the first days of the American invasion, into almost every town from Ysabella on the northwest coast to Humacao on the east coast, and then up the military road to this capital. In the districts of Guayama and Southern Humacao it was part of my business to investigate the cause of deaths among the natives. Everywhere I found the main cause assigned to be anemia and phthisis. Everywhere I went I was struck by this ever-prevalent anemia. The pale, yellowish, waxy skin, the bloodless lips, and the swollen, puffy features, formed a picture never seen by me outside of tropical Puerto Rico. Yet I soon found that these people had been living on rice, beans, maize, dried codfish and fruits. Meat very rarely entered into their diet. They and their fathers before them had lived exclusively on the diet urged by the public press as suitable for tropical climates, and the result filled the hospitals with such ghastly cases of anemia that no one who has once seen the picture can ever forget the impression. On the other hand, I soon discovered that the people who lived in the towns and could afford it ate two hearty meals daily. These people, I believe, use more meat than we use in American cities, and there is no doubt in my mind that I have used more meat and felt more need of it since I have been here than ever in the same time in the United States. Yet I am one of the few who did not have to go home for ill health; while the natives that eat in the hotels with me, and as freely as I do, are perfectly healthy individuals, and show not the least trace of anemia. Only a few days since, a native informed me with much gusto that one of the best things that Puerto Rico afforded was *chuleta de cerdo* (pork chops), surely one of the most unsuitable articles of diet

[1] Read before the Lyceum, Fort Douglas, Utah, January 25, 1901.

for a tropical climate, as our physiological friends will tell us, and yet the absence of which, in my opinion, made the native anemic to a noticeable degree. These observations are so common in this climate, and have been so forcibly impressed on me, that I feel more and more the wisdom of going very, very slowly in urging alterations in the ration."

Major Stephenson, Surgeon U. S. Army, also made the following statement: "My personal experience of a year in Tampa, Puerto Rico and Santiago was that I craved and ate as much meat of all kinds relatively to all food eaten in cooler climates. I believe that meat consumption among the natives of hot climates is limited to their purses, not to their tastes. In Cuba and Puerto Rico I found the noon and evening meals in private houses and restaurants prodigal of meats of all kinds."

The absurdity of arguing from theory and not from experience was forcibly impressed on me as I read on a balcony in San Juan the essay that gained the hundred dollar prize given by Major Louis Livingston Seaman for the ideal tropical ration. As I reached the part that discussed the "distaste for fats in considerable quantities, so early acquired in the tropics" I was aroused by the cry of the "Char-r-rone" vender. For more than a month I had noticed that same cry every afternoon. I had tried faithfully during that time to detect what he was calling out, but had as signally failed, until one evening I was fortunate enough to have an Englishman educated in Spain along with me when he made his rounds. Then I learned that "Char-r-rone" was the Puerto Rican abreviation for "chicharrones," and that this was Spanish for pork fried crisp with the skin on it. For twenty centavos I obtained a piece about a foot square. I found that while the outside was crisp the interior of my piece, an inch in thickness, was simply cold fat pork with a very little lean through it. The man sold it as a bonne bouche through the streets every afternoon. A couple of mouthfuls was all I desired to test, but the rapidity and relish with which my four little Puerto Rican girl friends devoured it gave me a striking example of the "distaste for fats in any quantity so early acquired in the tropics," and of the value to be attached to theories derived from analysis of "jibaro" dietary, as to what constitutes a suitable food for the tropics. On the other hand, it is now being claimed by some writers that the depression and languor of the tropics call for increased food and vinous stimulants, and this idea seems to be warranted by the large amount of meat, and of claret, or water with a dash of rum, used twice daily by the better classes of the population.

The board before which Major Seaman made his plea has recently, according to the public press, reported to the Secretary of War that, "The recommendation that the fresh meat ration be reduced in quantity was so opposed to all the teachings of experience, both in our country and in Cuba and Puerto Rico, that the board was unable to accept the recommendation as conclusive without further investigation. Two members of the board have served in Cuba and the third in Puerto Rico, and their personal experience has been that as much meat has been desired and eaten as in the United States, and with no deleterious effect on the health of the men. The natives of these countries are also large meat eaters when they are able to secure it, and the meat eaters are noticeably stronger and healthier looking than the poorer classes who from necessity are mainly vegetarians. The board also interviewed a number of officers and other persons that had been in the Philippines, and, taking all sources of information together, the board is of the opinion that it would be a mistake to make any fixed reduction in the meat ration." The criticism of General Henry in the above quoted article that, "The objection to the meat (of Puerto Rico) for an American is, that having no place to keep beef after being killed, it has to be put in the pot in a hot, quivering condition; and I believe this made many an American soldier ill," is in part well applied. Puerto Rican beef cannot be cooked American fashion and be other than tough and unpalatable, as it is killed about 3 o'clock in the morning, and eaten by 11 or 12 o'clock the same day. I had so fully recognized this fact that for more than a year before leaving the island I refused all "bifstek" or "rostbif," as presented by the seductive native. Only Swift or Armour refrigerated beef can in Puerto Rico be prepared American fashion. Native beef, however, prepared by native cooking, is tender and palatable, devoid of this objection and is habitually consumed with only the best results. In fact, when they ask us to replace the meat ration by vegetables we should not forget the Spanish motto that says: *Bellotas y tostones hacen malos trabajadores.*

BUBONIC PLAGUE.[1]

Report on the Plague in Manila, P. I., from Jan. 1, 1900 to June 30, 1900.

by joseph j. curry, m.d.

Captain and Assistant Surgeon, U. S. V., Philippine Medical Service; Member of the Board of U. S. Army Medical Officers to Investigate the Diseases of the Philippine Islands.

About the 1st of January, 1900, there were reported, from the walled city of Manila, a number of deaths with history of only few days illness — these cases occurring in the same block of dwellings. As the Board of Health was at this time without a laboratory equipment, Major-Surgeon Edie, U. S. Army, president of the Manila Board of Health, requested the assistance of the First Reserve Hospital laboratory. At the time I was in charge of this laboratory, and with the consent of Major-Surgeon W. R. Hall, U. S. Army, commanding the First Reserve Hospital, I placed the use of the laboratory, for the work of investigating

[1] Extract of a report to the Surgeon-General of the Army on the Diseases of the Philippine Islands. By permission of the Surgeon-General of the Army.

these cases, at the disposal of Assistant-Surgeon W. J. Calvert, U. S. Army, pathologist to the Board of Health. As in most of these suspicious deaths, there were reported to have been found greatly swollen glands. Bubonic plague was suspected, in spite of the assurances of the Spanish and native physicians that the plague never occurred in Manila.

I assisted Dr. Calvert, as did also Dr. Edwin R. Hodge, and Hospital Steward Musgrave, U. S. Army, in autopsies, with cultures, and in the experimental work. The greatest care was taken of the cultures, and in the inoculation and care of the animals. For nearly six weeks the plague work was carried on at the laboratory of the First Reserve Hospital. The disease was early shown to be bubonic plague.

Numerous cultures were made, and many animals inoculated, but no case of bubonic plague occurred as a result of this work in the laboratory. I continued the work on the plague in the months of March and April, at the Board of Health laboratory, during Dr. Calvert's absence in Japan. As Assistant-Surgeon Calvert will make a full report of *his* work later, it is unnecessary for me to go into details here.

I will confine myself to the statement of a routine method used in the examination of suspected plague cases, and to a few general remarks

ON THE DIAGNOSIS OF BUBONIC PLAGUE.

The plague bacilli do not appear in the blood until late in the disease, save in the rapid fulminating type. Blood *cultures* are therefore unsatisfactory, so also is the agglutination (Widal's) test with the plague bacillus, for an *early* diagnosis.

The most satisfactory method, I believe, is that of aspiration by means of a hypodermic syringe of one of the swollen glands, preferably, of one of the *recent* swollen glands. A hypodermic syringe with large caliber needle and tight plunger answers admirably. After cleansing and disinfecting the skin over the swollen gland, a few drops are withdrawn from the gland. The syringe may then be placed in a sterile box or a test tube and carried to the laboratory without danger. Now *three* things are to be done with the material in the syringe: (1) A drop is used to make cultures — best in melted agar tubes or in bouillon from which dilutions, cultures and plates can be made. (2) A drop is allowed to fall on a clean slide, which is then smeared by a platinum needle, to be used for direct examination. (Two preparations may be made from this.) (3) The remainder is injected into an animal (mouse, rat or other animal).

The plague bacilli occur in large numbers in the *glands* even early in the disease. The specimens on the glass slides are stained, one by Gram's method, and one with Zeihl's carbolic fuchsin, or Loffler's Methyl Blue. The presence of large numbers of characteristic short bipolar staining bacilli, which decolorize by Gram's method, makes the case at once more than suspicious. The cultures will be ready to examine and transplant on various differential culture media by the next morning. By the second day these latter cultures will be ready for examination. Usually by this time, or shortly after, the animal (if the plague bacillus is present) is either dead or very ill, and now an absolute diagnosis can be made. This method I used many times, and in *every instance* in which the direct coverslip examination showed large numbers of short, thick bacilli, which decolorized by Gram, the subsequent history of the case, the cultures, and the inoculations of animals proved the case to be one of bubonic plague.

The above applies to the bubonic type which was the type that prevailed in the great majority of the cases which occurred in Manila. In the pulmonic type the plague bacilli occur in enormous numbers in the bloody expectoration, and are readily recognized on direct coverslip examination of the expectoration.

Sometimes bubonic plague is ushered in with a sudden chill, followed by a fever simulating closely a malarial attack. The examination of the blood in these cases fails to reveal the malarial parasite, and the blood shows a *marked leucocytosis early*. This would arouse suspicion of a septic process of some kind, and direct the observer to look carefully for a cause of the leucocytosis.

I was enabled to detect a case of plague in a very early stage, occurring in the walled city close to the army headquarters, by having my attention directed by the *blood examination* for the *malaria* and finding this condition, that is, absence of malarial parasites and presence of marked leucocytosis. This man died two days later at the plague hospital, and at the autopsy the case was found to be a very acute case of bubonic plague.

GENERAL REMARKS ON THE MANILA CASES.

There were recognized from January 1 to June 30, 1900, in Manila, 225 cases of bubonic plague, with 167 deaths, which equals a mortality of 74%. Of this number of cases of plague 160 were Chinese, with 115 deaths; 63 natives, with 15 deaths; and 2 Americans, with 1 death. It is rather surprising to find the death rate higher in the cases among the natives than among the Chinese. The native death rate in this series is nearly 81%, while the Chinese is not quite 72%. When the surroundings are considered, and manner of living, it would be expected that the Chinese would present a much higher percentage of fatality than the Filipinos. I am at a loss to account for this higher mortality among the natives in Manila.

There were no cases of plague discovered among the Spanish or foreign residents of Manila, and but 2 among the Americans. These 2 cases were in civil employees of the Quartermaster's Department of the Army, who were employed at Hall's *Corral* in Manila. One of these men died, and the other recovered after a moderately severe attack.

Mode of infection. — It was noted that the *right* femoral and *right* inguinal glands were

usually the first glands to enlarge. In considerably over one half of all cases these glands were enlarged first. The right femoral and inguinal glands were primarily enlarged nearly three times as often as the corresponding glands on the left side. It was unusual to be able to locate any fresh wounds of the extremity which appeared to be the point of entry of the infection. It was very common, however, to find skin lesions involving legs and thighs. Dhobie itch (so called) is very common among the natives, and the crotch is a favorite site for this infection. There is the possibility of introduction of the plague bacilli through infection of these areas (in which the epidermis is broken) by scratching. (As most people are right-handed, it may be possible that they are more inclined to scratch the right thigh than the left.)

It would be of interest to know if in other epidemics the right inguinal glands were *primarily* involved as frequently as in those cases which we studied in the Manila epidemic. Fleas and mosquitoes are always abundant in the Philippine Islands. Almost all cases of plague which came to autopsy showed evidence of bites by these pests. The possibility of the spread of plague by insects has been shown by the Japanese and other observers. It does not seem probable that mosquitoes play any part in the dissemination of the plague.

Objection has been made by some to the puncture of a plague gland with the hypodermic needle. These observers claim there is danger of causing general infection by this method from rupture or injury of a blood vessel, which would allow the plague bacilli to enter vessel and, by it, the general circulation. I think that this objection to the use of the aspiration method for diagnostic purposes is based more on theoretical than on practical grounds. I believe it much *safer* for both the patient and operator than the incision method as advocated by some.

Clinical Department.

A CASE OF RETROPERITONEAL LYMPHANGIOSARCOMA; OPERATION; RECOVERY — NO RECURRENCE AFTER TWO YEARS.[1]

BY T. B. LUND, M. D., BOSTON.

ON February 13, 1899, I saw, in consultation with Dr. W. T. Patch, of Boston, G. W. B., a salesman, fifty-eight years of age, who had been obliged to give up his work by an attack of influenza in December, 1898. The attack of influenza had left him weak and miserable and he had, during January, 1899, suffered from pain in the epigastrium, extending into the left side and back. Two weeks before I saw him he had a sudden attack of pain in the epigastrium, with vomiting. His bowels had been very loose during his illness, and his movements occasionally tinged with blood. He thought he had lost eighteen to twenty pounds in the last two months. His only previous illness had been an attack of typhoid fever eight years ago, and he was in good health when attacked by influenza.

We found him in bed at his home, a rather florid, flabby-looking man, with a temperature of 99.4°, pulse 80, and of fair strength, lips and extremities rather blue. His abdomen was lax, tympanitic, and not markedly tender. In the left lumbar and hypochondriac regions, extending inward as far as the median line, was a rounded, fluctuating tumor, larger in size than a fetal head at term. The tumor, from its location, suggested a tumor of the left kidney, and its fluctuation suggested a hydronephrosis. Such a diagnosis also was consistent with its recent appearance and unusually rapid growth. Mr. B. was brought to the City Hospital, and rested comfortably in bed for a few days, having no pain, and a normal pulse and temperature. The urine showed no albumin or evidence of renal disease.

On February 18th he was given ether, and by means of the Harris urine separator an attempt was made to obtain the urine from each kidney. The specimens obtained from each side of the instrument varied only in that one contained a larger percentage of urea than the other. Pressure upon the tumor seemed to cause a faster flow of urine from the left side of the instrument. The tumor, repeatedly aspirated through the loin, gave no fluid except a few drops of blood.

Under the circumstances it was thought best to perform an exploratory operation and deal with the tumor according to the conditions as found. The means so far employed had not sufficed to clear up the diagnosis, but had rendered that of hydronephrosis improbable, and that of a tumor of the kidney, which would seem from its soft consistency and rapid growth to be malignant in character, more probable. Therefore on February 23, 1899, the patient was again etherized, placed on the right side with the body flexed over a sand bag, and an incision was made from the tip of the twelfth rib to the crest of the ilium, parallel to the outer border of the erector spinæ. After incising the transversalis fascia, there was found in the retroperitoneal space, apparently below the kidney, the surface of a large, fluctuating tumor, which consisted of a fibrous sac, over the surface of which were spread several very large veins, running in a direction parallel to the spine. Aspiration of the tumor yielding only a few drops of blood, an incision was made into the sac, and it was found to contain a soft, dark-red, malignant-looking material, having the appearance and consistency of currant jelly. The incision was then enlarged sufficiently to admit the hand, and a very large quantity, more than a quart, of this red, jelly-like material removed with the hand and a large curette from the interior of the sac, which appeared to extend upward and forward in front of the kidney. There was considerable hemorrhage from the interior of the sac, and the patient col-

[1] Read before the Surgical Section of the Suffolk District Medical Society, February 6, 1901.

lapsed and became pulseless, so that it was evidently impracticable to attempt to remove the sac, which was therefore washed out, rapidly packed with several strips of iodoform gauze, and the wound partially sutured. Subcutaneous infusion of normal salt solution was then performed, and under this, and stimulants given subcutaneously and by the rectum, the patient gradually came up, and by evening had a pulse of 140. During the next few days he did well, and the course of the wound was aseptic. The pathologist's report, by Dr. F. B. Mallory, was as follows:

Microscopically the tumor is very cellular. It is largely made up of long, narrow, branching canals or spaces, lined for the most part with low, flattened cells; in places, however, the cells are taller and approach the cuboidal shape. The canals contain an almost perfectly homogeneous material. In parts of the tumor the cells are packed very closely together, so that little or no evidence of spaces can be made out, and the cells assume more or less of a spindle shape. The connective tissue stroma is slight in amount, but contains many dilated lymph spaces, which, like the canals first mentioned, contain a homogeneous material, and in places many lymphoid and plasma cells.

Diagnosis.— Lymphangiosarcoma, or perhaps better, lymphangio-endothelioma.

We had here to do with a tumor of which the rapid growth, the vascular appearance of the covering sac, the macroscopical appearance, and the microscopical examination confirmed the diagnosis of malignancy. It was also in the highest degree probable that we had not accomplished its complete removal, both because we had not excised the fibrous sac, and had perhaps left some fragments of the jelly-like contents adherent to the interior of the sac. Therefore, in view of the probability of recurrence, it was determined to try the erysipelas and prodigiosus toxins of Coley. On March 14th, the patient being in fair condition, and the wound reduced to a clean granulating sinus with slight serous discharge, 1 minim of the serum was given. It was gradually increased to 10 minims, but on April 14th, as the patient, who had developed a right femoral phlebitis, had a slight cough and pain in the chest, seemed in a critical condition, and as several small abscesses had developed at the site of the injections, it was deemed wiser to discontinue the administration of the toxins.

After this the patient made a gradual recovery, left the hospital on April 24th, and after spending the summer in western New York, returned to Boston restored to health, and resumed his employment as a salesman in one of the large department stores. He has been regularly engaged in his employment since, has gained markedly in weight and strength, and suffers only from swelling of the right leg, which is undoubtedly one of the results of the phlebitis which followed the operation. There is no evidence of the recurrence of the tumor at the present date, two years after the operation.

The case is reported on account of the rarity with which a tumor of malignant macroscopical and microscopical appearance is cured by operation, and goes to show that all tumors of malignant appearance and rapid growth are not, at least, actively malignant. It does not seem to me probable that the treatment by the mixed toxins had anything to do with the non-recurrence in this case, as, owing to its apparent bad effect upon the patient's general condition, the toxins were given only in small amounts and for a comparatively short time.

VOMITING OF PREGNANCY. — SUSPENSION OF PREGNANT UTERUS. — EXTRA-UTERINE PREGNANCY. — OPERATION FOR FIBROIDS.

REPORTED BY J. OSWALD VOGEL, M.D.,
From the Service of Frederick William Johnson, M.D.

CASE I. *Vomiting of Pregnancy.*—Nellie C., twenty-one, single. Entered the medical service of the Carney Hospital, September 28, 1900, with the following history: For the past four months has had poor appetite, with occasional nausea and belching after eating. Ten days ago the patient vomited in the morning and several times during the day. There was no blood in the vomitus. The vomiting has continued ever since, coming on both during the day and during the night. Has lost about 8 pounds, although the appetite is fair. Bowels constipated. Physical examination was negative throughout. The white count was 8,200. The urine was acid, of a specific gravity of 1,012; no albumin, no sugar. Since entrance the patient has vomited repeatedly, irrespective of time and feeding. No blood in vomitus; no pain; temperature and pulse normal; no epigastric pain or tenderness; no sign in breasts of pregnancy. Rectal feeding was ordered. By mouth oxalate of serium and bismuth subnitrate, and by the rectum $\frac{1}{3}$ grain of cocaine were given. No effect was produced on the vomiting.

October 3d. Dr. Johnson found the uterus enlarged and somewhat to the right side of the pelvis. Cervix soft; violet color of vagina well marked. The diagnosis of probable pregnancy was made.

October 6th. In spite of every variety of treatment, the vomiting still continued, everything taken by the mouth being promptly rejected. The patient first menstruated at fifteen. Regular every four weeks until she came to this country in November, 1899, when she did not menstruate for two months. Was then regular up to June, 1900, when she did not flow for six weeks. Was unwell in July and August; but has not flowed any since August 20.

October 11th. When etherized, a positive diagnosis of pregnancy was made. The cervix was slowly and carefully dilated to the width of an inch. Then the cervical canal was thoroughly painted with Churchill's tincture of iodine from external os to inside internal os.

October 12th. Some vomiting from the ether. On rectal feeding.

October 13th. Vomited once. Rectal feeding stopped. Semi-solid food given.

October 15th. Was put on house diet.

October 18th. No trouble in retaining all kinds

of food. The cathartic pill taken at night caused vomiting.

October 24th. No vomiting since the 18th. and no vomiting of food since the 15th. Discharged well.

This is the second case of the persistent vomiting of pregnancy relieved by this method of treatment by Dr. Johnson.

Case II. *Suspension of pregnant uterus.*— Mary F., twenty-eight, married. Entered Carney Hospital November 6th, and was operated on November 8, 1900. A diagnosis of three months' pregnancy complicated with an ovarian cyst was made by her family physician, Dr. G. N. P. Mead. An incision 4 inches long was made to the right of the median line, through the right rectus muscle. The intestines were found adherent to the posterior surface of the uterus on the left. A cyst of the right ovary with twisted pedicle was found adherent to the posterior surface of the uterus and to the rectum. This cyst was the size of an orange, and was filled with dark, inky-looking material, apparently due to hemorrhage from the cyst wall. In separating the adhesions, the cyst was ruptured. The sac with right tube was removed, the tube being dissected out of the horn of the uterus, as has been Dr. Johnson's custom for years. The uterus was the size of a three months' pregnancy. The left ovary, the size of a hen's egg, was so incorporated in the cyst wall that it appeared part of it, and it took some time to decide from which side the cyst grew. The diseased portion of the left ovary was removed, leaving a rim of apparently healthy ovarian tissue, which was sewed over and over with catgut. The uterus was then suspended, after Kelly's method, with two sutures of kangaroo tendon. A quart of normal salt solution was poured into the peritoneal cavity. The abdominal incision was closed (as has been Dr. Johnson's custom for years) layer by layer, with animal ligature material, except the skin, which was united with silkworm gut. The convalescence was uneventful, and she was discharged well twenty-three days after the operation. Pregnancy has continued up to the present day with no discomfort.

This case is reported on account of the unusual procedure of suspending the uterus three months pregnant, and on account of the complication which existed with the pregnancy.

Case III. *Extra-Uterine Pregnancy.* — A. N., thirty-three, married. No children. One abortion at four months, seven years ago. Menstruation began at sixteen; always regular; flows three days; uses but three napkins. No dysmenorrhea. Peritonitis lasting one month followed the abortion seven years ago. No leucorrhea. Menstruated last, November 24, 1900; flowed the usual amount; no pain. December 25, 1900, at 2 A. M., was suddenly taken with pain in the lower abdomen. The pain was not confined to either side, and lasted several hours. Returned in forty-eight hours very severely and lasted two hours. These pains returned, off and on, for several days, requiring the use of morphine. Was never entirely free from discomfort in the abdomen. Was kept quiet in bed from December 27, 1900. until she was removed to the hospital January 25, 1901.

January 6th. A dark, bloody discharge began from the vagina, and continued up to the time of the operation. Often soaked through three napkins a day.

Nausea and vomiting were present during the interval from December 27th to January 25th.

Examined January 25, 1901. There was a dark brown, non-offensive discharge from the vagina. Uterus enlarged and in good position. Fibroid at the fundus extending toward the right. Sensitive mass, with boggy feel, behind and to the right of the uterus. Temperature normal; pulse 90.

Operation. — Considerable tissue was curetted from inside the uterus. On opening the abdomen, the right tube was found dilated half way between its uterine and fimbriated ends to the size of a pullet's egg, and with lymph and partially organized blood around it, made a mass the size of a small orange. The tube was unruptured; the escape of blood had been from the fimbriated end. The right tube and ovary were removed, the tube being dissected out of the horn of the uterus in the usual way. The parietal peritoneum was thickened, considerably injected, and in places the intestines were adherent to it. The bladder was adherent to the intestines, the ileum and cecum adherent to each other and to the iliac fossa. The appendix was hypertrophied, covered with adhesions, and adherent to the cecum and to the gestation sac. The mesosalpinx was greatly thickened. On the left side there was old pelvic peritonitis. A fibroid the size of a goose egg was situated in the fundus. This was enucleated, and the opening in the uterus closed with catgut. The appendix was inverted into the cecum and the edges stitched over with over-and-over suture of plain catgut. The uterus was suspended after Dr. Kelly's method. A pint of normal saline solution was poured into the abdominal cavity, and the abdominal wall was sewed up in four layers. The patient made an uneventful recovery.

Case IV. *Operation for fibroids.* — After a long search, I can find but 2 cases similar to this one on record. One was reported by Dr. George H. Washburn, of Boston, and the other by Dr. Howard A. Kelly, of Baltimore. The unusual condition was due to the fact that the fibroids originated from the cervix and lower segment of the uterus. As they developed they grew downward into the pelvis, and as they filled this space they gradually pushed the uterus up, so that at the time of the operation in this case, it reached to the umbilicus, riding on the top of the mass, and reminding one of the howdah on the back of an elephant. In front and behind, the tubes, ovaries, round ligaments and uterus were visible and of normal size and appearance. From about the cervical junction a mass spread downward, filling the pelvis and containing forty-three separate fibroids.

E. W., thirty-three, married. Was curetted four years ago for hemorrhage. Menstruation is

regular every four weeks; but of late there has been an increase in both the duration and the quantity of the flow. There is severe dysmenorrhea, beginning two days before the flow. The pain is in the back and lower part of the abdomen, and continues throughout the flow. Between menstrual periods there is a constant backache, with sagging and dragging down. For five years the patient has been able to feel a hard mass in the lower part of the abdomen. Has never had any children. Feet swell at times. Urine normal. On vaginal examination a round, smooth mass was found filling the pelvis. No cervix could be found. An incision was made, in the usual way, to the right of the median line through the right rectus muscle, about six inches in length. No cervix could be found, nor was it seen at any time during the operation, it having been so drawn out and incorporated into the fibroids that it was indiscernible. Extending out on either side underneath the peritoneum were what appeared to be two large masses of fibroids filling the pelvis. The mass on the left extended into the left broad ligament to the pelvic wall. The blood supply to the uterus was completely shut off, then the large mass was enucleated posteriorly. This mass extended beneath the uterus over to the symphysis. Then another mass on the left, extending out to the pelvic wall, was enucleated. This was of the size of a large orange, was of a very soft consistency, and was made up of a great number of small tumors. After emptying the pelvis of fibroids, a hysterectomy was done. The wound was closed, layer by layer. The patient made an uninterrupted recovery.

Medical Progress.

PROGRESS IN PATHOLOGY.

BY JAMES H. WRIGHT, M. D., BOSTON.
Director of the Clinico-Pathological Laboratory, Massachusetts General Hospital.

MALARIA AND MOSQUITOES.

THE Italian observer Grassi has recently stated that, as a result of his studies in Italy, the geographical distribution of malaria and certain species of anopheles are coincident, and that these species of mosquitoes are not found in non-malarious districts. He also states that this coincidence is probably true for other parts of the world. Celli [1] has recently denied these conclusions, for he found anopheles in healthy situations in Italy which had never been malarious. More recently Nuttall, Cobbett and Strangeways-Pigg [2] have published an elaborate study of this question, based upon observations in England. Although malaria has apparently disappeared from England, they find three species of anopheles, not only in districts which were formerly malarious, but also in places in which malaria has never been known. The conclusion of Grassi, therefore, that anopheles are not to be found in non-malarious districts, is abundantly disproven, and it further appears that the disappearance of malaria from England is not dependent upon the absence of anopheles.

The disappearance of malaria from England is considered by them as probably due to the following causes: (1) A reduction of the number of mosquitoes consequent upon the drainage of the land; (2) the reduction of the population in infected districts as the result of emigration about the time when malaria disappeared from England; (3) the use of quinine.

The first mentioned cause seems to the authors to have been chiefly operative. They are inclined to think that there may be another intermediary host for the malarial parasite besides man, and that this host may have become extinct in the lowlands where it is known that the fauna and flora have altered. As a further result of their observations they conclude that the numerical distribution of the anopheles is more important than their geographical distribution. The existence of anopheles in known malarious districts, they think, will explain the occasional occurrence of malaria in out-of-the-way places without making it necessary that malaria-bearing mosquitoes have been freshly imported, for under suitable conditions of temperature and the requisite number of anopheles, a malarious subject coming from other parts might well infect the local insects which in turn would spread the infection to healthy persons.

SARCOMA OF THE INTESTINE IN THE ILEOCECAL REGION.

Blaul [3] reports 2 cases of sarcoma in this situation, and summarizes 6 other cases which he has found in literature. All 8 cases were round cell sarcoma, with a relatively small amount of stroma. The tumor formations took the form of a marked thickening and infiltration of the intestinal wall, but without narrowing of the lumen of the intestine, except in 1 case. With the exception of this single case no symptoms of intestinal obstruction were observed.

The author points out that the absence of symptoms of obstruction may be of clinical significance in the differential diagnosis from carcinoma and tuberculosis. In the majority of cases the tumor ceases at the peritoneal surface, yet it may happen that this may be broken through and an enormous tumor development occur external to it. Adhesions to neighboring structures occur, but are not the rule. The production of metastases varies. In general it comes early, and may involve a great number of organs. The mesenteric and retroperitoneal lymphatic glands are usually the seat of secondary growths.

THE STRUCTURE OF CARCINOMA.

Peterson [4] thus summarizes his study of carcinoma of the skin by reconstruction methods and serial sections.

[3] Arch. Patholog. Anat. u. Physiol. u. Klin. Med. Bd. 162, H. 3.
[4] Verhandl. der deutsch patholog. Gesellsch. auf der 72 Versammlung deutsch. Naturforscher und Aerzte zu Aachen vom 16 to 22, September, 1900.

(1) The masses of epithelial cells of a carcinoma are continuous with one another, belonging to a single trunk from which in all directions branches and processes arise. The so-called cancer alveoli are nearly always sections of these processes. Isolated alveoli, that is, islands of epithelial cells altogether surrounded by connective tissue, are very rare. The discontinuity of growth of the epithelial cells, therefore, does not belong absolutely to the conception of carcinoma.

(2) With regard to the starting point of the neoplasm two forms may be differentiated; (*a*) The unicentric carcinoma; the growth of epithelial cells begins at a single point and spreads from this throughout the whole neighborhood and also to the neighboring epithelium. In this way microscopical pictures can easily arise which simulate an active growth of this neighboring epithelium. (*b*) The multicentric carcinoma; the epithelial cell growth begins at different points, and the different masses of epithelial cells become combined only secondarily. The separation of these two forms of carcinoma, which can only be made with difficulty by pure microscopical observation, can easily be made by means of the reconstruction method.

(3) The certain proof that multicentric carcinoma exist is a further strong confirmation for the belief that the first beginning of carcinoma is to be sought for in the epithelial cells and not in the connective tissue.

THE ETIOLOGY OF YELLOW FEVER.

Walter Reed and James Carroll[5] publish the results of an exhaustive study of the biological characters and pathogenesis of the bacillus X. of Sternberg, of the bacillus icteroides of Sanarelli and of the hog-cholera bacillus.

They appear to have settled beyond a doubt that the bacillus X. of Sternberg is not identical with the bacillus icteroides of Sanarelli. Their conclusions are as follows:

(1) Bacillus X. (Sternberg) belongs to the colon group.

(2) Bacillus icteroides (Sanarelli) is a member of the hog-cholera group.

(3) The various channels of infection, the duration, of the disease and the gross and microscopical lesions in mice, guinea pigs and rabbits are the same for bacillus icteroides and for the hog-cholera bacillus.

(4) The clinical symptoms and the lesions observed in dogs inoculated intravenously with bacillus icteroides are reproduced in these animals by infection with the hog-cholera bacillus.

(5) Bacillus icteroides when fed to the domestic pig causes fatal infection, accompanied by diphtheritic, necrotic and ulcerative lesions in the digestive tract, such as are seen in hogs when infected with the hog-cholera bacillus.

(6) This disease may be acquired by exposing swine in pens already infected with bacillus icteroides, or by feeding them with viscera of infected pigs.

(7) Guinea pigs may be immunized with sterilized cultures of bacillus icteroides from a fatal dose of the hog-cholera bacillus and *vice versa*.

(8) Rabbits may be rendered immune by gradually increasing doses of a living culture of bacillus icteroides of weak virulence from a fatal dose of a virulent culture of the hog-cholera bacillus.

(9) The sera of animals immunized with bacillus icteroides and with the hog-cholera bacillus, respectively, show a marked reciprocal agglutinative reaction.

(10) While the blood of yellow fever practically does not exercise an agglutinative reaction upon bacillus icteroides, the blood of hog cholera agglutinates this bacillus in a much more marked degree, thus pointing, we think, to the closer etiological relationship of this bacillus to hog cholera than to yellow fever.

In a later publication these same investigators, in conjunction with A. Agramonte and Jesse W. Lazear,[6] report that they failed to find bacillus icteroides either in the blood during life of 21 patients in various stages of yellow fever, or in cultures from the blood and organs at 11 autopsies of yellow fever patients.

As a result from the studies contained in these papers it seems very probable that the bacillus icteroides is not the cause of yellow fever, and that when it is observed in cases of yellow fever it is only a secondary invader.

In the second paper some very interesting observations are offered which strongly suggest that the mosquito may be the intermediate host for the infecting agent in yellow fever.

PRIMARY SARCOMA OF THE STOMACH.

Since Schlesinger, in 1897, published his analysis of of 36 cases of primary sarcoma of the stomach, which number included 33 cases in literature and 3 cases of his own, the number of recorded cases has increased to the neighborhood of 50.

W. Mintz,[7] in a gratifyingly short paper, reports an additional case, and gives a very readable summary of our present knowledge of this affection. He points out that the most frequently observed forms of sarcoma are lymphosarcoma and round cell sarcoma. These new growths do not occur in the form of projecting nodules, but assume the character of an infiltration and thickening of the stomach wall of varying extent. They are prone to form metastases in other organs.

The disease apparently is more frequent between the twentieth and thirty-fifth year. Men are more frequently attacked than women. In general the symptoms are those of cancer of the stomach, and in only a few cases has the proper diagnosis been made during life. In one of these the diagnosis was made by microscopical examination of a small particle obtained in the stomach washings. In the cases in which a chemical examination of the stomach contents was made, lactic acid was present, but hydrochloric acid absent. Mintz thinks that the starting-point of the sar-

coma in his case was the lymph-nodes which are normally present in the submucosa near the pylorus.

LATENT TUBERCULOSIS OF THE PLEURA.

The occurrence of small, circumscribed, fibrous nodules on the pleura is frequently observed at autopsies. The nature of these nodules has not received much attention at the hands of pathologists. They have been called miliary fibromata by some. Weigert, in 1883, pointed out that these nodules cannot be distinguished from old miliary tubercles of the pleura, but his paper has hitherto been the only careful treatment of the subject.

In a recent paper E. Hodenpyl[8] reports the results of his examination of the pleural surfaces in 131 autopsies apparently consecutive. The ages of the individuals varied from fourteen to ninety-two years. In 45 of the autopsies in which the lungs were free from tuberculosis, or in nearly 50% of all the cases, nodules were present, which he found, on careful histological examination, were undoubtedly of tubercular origin.

THE SPOROTHRIX OF SCHENCK IN SUBCUTANEOUS ABSCESSES.

L. Hektoen and C. F. Perkins[9] report a case of refractory subcutaneous abscesses of the arm, in the pus from which a fungus was found apparently identical with the sporothrix described by Schenck in 1898. The pathogenic effects upon experimental animals produced by this organism were in only a slight degree different from those which Schenck observed. The authors emphasize the point that in the lesions of the animals the organism appears only in the spore form, and does not develop the mycelial threads which it does in cultures. The histological lesions produced are necrosis and pus formation accompanied by development of granulation and fibrous tissue. The human lesions were not studied histologically.

THE ETIOLOGY OF ACUTE PANCREATITIS AND FAT NECROSIS.

E. L. Opie[10] offers a most plausible explanation of many cases of acute pancreatitis and fat necrosis. He considers that these conditions can be brought about by the lodgment of a gall stone in the common duct, near its lower extremity, by which the pancreatic duct would be obstructed. As soon as the pancreatic duct is thus totally obstructed, the damming up of the pancreatic secretion would be followed by its escape into the surrounding tissues, and consequent production of necrosis and various lesions in the pancreas itself. The invasion of intestinal micro-organisms would likewise easily occur, and they in turn would contribute to the necrotic and inflammatory process.

In order to bring about these results the obstruction of the bile duct and the pancreatic duct by the stone need not be long continued, but may be transient, so that the existence of signs of such an obstruction may be overlooked at the autopsies.

In support of this view of the origin of acute pancreatitis and of fat necrosis, he points out that in more than 30 cases of acute lesions in the pancreas and of fat necrosis in the parapancreatic fat tissue the coincidence of cholelithiasis has been observed. In 8 cases, including one case observed by himself, a gall stone was found either in the common duct near its orifice, or in the duodenum with evidence of recent passage from the gall duct. That the damming back of the secretions in the ducts of the pancreas may lead to fat necrosis, Opie has previously shown by experiments on cats.[11]

Opie calls attention to the fact that only one individual in three is without an excessory duct of the pancreas opening by a separate orifice into the duodenum, so that in the majority of individuals the obstruction of the main pancreatic duct, in the manner above indicated, would probably not be followed by lesions in and about the pancreas.

THE DEMONSTRATION OF TUBERCLE BACILLI IN SPUTUM AND URINE.

[12] G. Jochman proposes a method for increasing the numbers of tubercle bacilli in specimens of sputum and urine, so that they may be more readily demonstrated by microscopical examination.

The method for sputum consists in mixing 10 cubic centimetres of the sputum with 20 cubic centimetres of a special culture fluid and keeping the mixture in the incubator for twenty-four hours. At the end of this time 3 cubic centimetres of liquefied carbolic acid is added to the mixture and shaken until a milky emulsion is formed. A sediment is allowed to form and this is examined for tubercle bacilli.

For urine the usual amount required for obtaining a centrifugalized specimen is taken. After it has been centrifugalized the supernatent fluid is poured off from the sediment and replaced by some of the special fluid. The centrifuge tube is then placed in the incubator for twenty-four hours, after which the sediment is examined as usual for tubercle bacilli.

Jochman claims that by this method any tubercle bacilli that may be present in these fluids are greatly increased in number. The special fluid which he uses is essentially Hesse's culture medium for tubercle bacilli, minus the agar agar. It has the following composition: Nahrstoff Heyden, 5 grammes; sodium chloride, 5 grammes; glycerine, 30 cubic centimetres; sodium bicarbonate solution (28.6 to 100), 5 cubic centimetres; water, 1,000 cubic centimetres. The Nahrstoff Heyden is a proprietary preparation of the same class as somatose and other proteid trade products. The virtues of this fluid are due to the fact that the tubercle bacillus thrives better in it than do other bacteria.

In a later paper[13] Jochman advocates an acid

rather than an alkaline reaction for the culture fluid. For the purpose of producing an acid reaction he recommends the addition of a 1% solution of lactic acid in the proportion of 10 drops to 50 cubic centimetres, or about 10 cubic centimetres to 1 litre.

PATHOGENIC BACTERIA IN MILK.

E. Klein[14] has made bacteriological examination of 100 samples of "country" milk. In 7 samples he proved conclusively the presence of the tubercle bacillus. This is a somewhat lower percentage than those obtained by other reliable observers whose percentages varied between 14% and over 71%. In one of the samples the diphtheria bacillus was present.

THE BACTERIAL SELF-PURIFICATION OF STREAMS.

E. O. Jordan,[15] from the results of his study of chemical and bacterial conditions of the Illinois River and its tributaries, concludes that sedimentation and exhaustion of the food supply by the bacteria themselves are the most potent factors in the disappearance of sewerage bacteria from river waters. He says that "it is noteworthy that all the instances recorded in literature, where a marked bacterial purification has been observed, are precisely those where the conditions have been most favorable for sedimentation."

New Instrument.

A TABLE FOR X-LIGHT EXAMINATIONS.

BY WILLIAM ROLLINS, BOSTON.

Dr. F. H. Williams has used for several years a stretcher on fixed supports. In the arrangement described in this note I have retained his stretcher, abandoning the fixed supports for several reasons:

(1) It is desirable to always stand in the same relation to the spark-gap and break handles, in order to control the wave length and intensity of the light without removing the eyes from the fluoroscope; moving the patient from right to left, or the reverse, to bring any part of his body under observation.

(2) It is important to be able to tip a patient; for example, in photographing stone in the bladder. If the patient is placed face down, with his head lower than his feet, the stone falls away from the shadow of the pelvis, in a distended bladder, coming so near the sensitive plate as to ensure a sharp picture, if light of proper wave length is used.

(3) In using a light above the patient a flat support for the plate is an advantage, while in placing a plate under a patient he need not be disturbed, one end of the stretcher being raised enough to allow the plate to be slipped between the stretcher and the top of the table. A suitable table is shown in Fig. 1. Length, 214 centimetres; width, 66 centimetres. The top is made of cross-glued veneers in sections, that any part may be removed. The underside is coated with aluminum paint to act as a static screen when grounded. The notched pieces holding the stretcher can be removed to allow the patient to lie flat on the table.

In my last note several precautions were mentioned which should be taken when making examinations by x-light. One of these, the non-radiable tube box, is shown in Fig. 1, with a stand having the necessary movements. We should be able to quickly measure the motion of the tube relatively to the median line of the patient, because in taking stereoscopic pictures or two photographs on the same plate, with the light in two different positions, a record must be kept. By graduating the arm carrying the tube box this is easily done. When the pointer is at zero the radiant area of the target should be in the same vertical plane that passes through the patient's medial line. Williams has shown that it is imperative for the right interpretation of an x-light negative to know the position of the source of light. As far as possible the record should be automatic. One way to accomplish this is shown in Fig. 1, at L.W. A straight wire is placed between the patient and the light. If the long axis of the wire is in line between the radiant area on the target and the plate, the image of the wire is a round dot. If in some other position, it shows as a line, whose length and direction give valuable information.

The authorities of Honolulu and the Hawaiian Islands, according to the *New York Medical Journal*, have determined that the recent great increase in the death rate from tuberculosis is due to the importation of the disease. A bill has been prepared and will be brought before the territorial legislature prohibiting the landing in the Hawaiian Islands of any person suffering from tuberculosis, or other contagious or infectious disease.

Reports of Societies.

THE OBSTETRICAL SOCIETY OF BOSTON.

MALCOLM STORER, M. D., SECRETARY.

MEETING of May 15, 1900, the President, DR. ALFRED WORCESTER, in the chair.

DR. A. C. JELLY, by invitation, read a paper entitled

PUERPERAL INSANITY.[1]

DR. J. G. BLAKE: The fact that in the very large number of obstetrical cases I have attended in the past I have met with but very few of puerperal insanity, leads me to corroborate the statement of the reader as to its rarity. I was about to refer to one of the cases Dr. Jelly has mentioned, in which, although the patient finally recovered completely, she had to go to the hospital during each attack. In several cases I have noticed an entire indifference to the baby, the mother's interest in the child being of very slow growth.

DR. C. F. FOLSOM spoke of the probability of many of the acute cases being of septic origin, and expressed the opinion that fresh air and plenty of nourishment were of much more importance than hypnotics in treatment.

DR. W. N. BULLARD: I think a very important question is the proportion of cases that are really puerperal insanity as compared with those that are merely some other form of insanity induced by the puerperium. Of course if puerperal insanity is induced by sepsis it would be probable that many of such cases were merely cases of pre-existing insanity lit up by sepsis. While I have seen fewer cases of puerperal insanity in the last few years, I am somewhat skeptical about the part sepsis plays.

DR. H. E. MARION: I should like to ask the reader as to the fixity of the rule he has laid down as to interference with pregnancy on account of insanity being contra-indicated. I recently saw a case of puerperal insanity in which the patient had several times been forced to go to an asylum for six months at a time. I advised emptying the uterus, with the happiest results as regards the mother.

DR. J. P. REYNOLDS emphasized the rarity of the condition and the advantages of home treatment when possible.

DR. G. J. ENGELMANN: I can testify as to the ease and promptness with which the sometimes intense nervous disturbances of pregnancy can be checked by the induction of labor. I have not happened to see many cases following labor. I have been in the habit of thinking that the decreasing frequency of puerperal insanity is due to the improved technique of obstetrics — the earlier use of the forceps, etc.— rather than to improved technique in asepsis, by perhaps lessening the woman's dread and shock.

DR. ALFRED WORCESTER: I have myself had a very sad experience with the few cases I have

[1] See page 271 of the Journal.

seen, so much so that the advent of puerperal insanity seems one of the most dreadful things that can happen. I can recall five cases in about a thousand cases of obstetrics, and four of these five were fatal. None went to an asylum. One fatal case was suicide, she having previously killed her baby and another child. She had shown unmistakeable signs of insanity in previous confinements. I cannot help thinking that puerperal insanity is escaped only barely in many cases. I have often noticed symptoms that seemed to me threatening — cases in which everything else was favorable. When I see a woman becoming suspicious when such a thing is utterly foreign to her nature, or unwilling to see her children or husband, I think that it should be taken account of, and I always am at pains to separate such a mother from her family, and warn the nurses to keep the sharpest kind of a lookout. I can recall several cases in which the woman acted in a strange way in the first few days after labor, such as getting up and wandering about the house when not watched. I cannot but help feeling that it would be a disadvantage to lull our professional brothers into a feeling of overconfidence and security about puerperal insanity. I think increasing emphasis should be laid on the necessity of guarding in every possible way the mental processes of the mother during pregnancy and labor; the necessity of giving the mother complete physiological rest before and after confinement rests heavily on us.

To sum up, I feel that aside from all provoking causes there is in the physiological drain of pregnancy and confinement a large predisposing cause for mental lesions that should be carefully borne in mind. Two of my four fatal cases were very directly associated with albuminuria. I agree with the reader as to the desirability of keeping these cases at home, if the home can be turned into a hospital, but that can be done only rarely. I feel that when it comes to the question of artificial feeding, the patient is much better off in a hospital than at home.

Recent Literature.

An Introduction to Physiology. By William Townsend Porter, M.D., Associate Professor of Physiology in the Harvard Medical School. Cambridge, Mass. The University Press. 1900.

Dr. Porter's work must be regarded as a practical contribution to the solution of the very urgent problem of education in the medical sciences. Teachers of these branches in our best medical schools are agreed that it is necessary to bring the student into direct contact with the facts he is studying, so far as possible, and that purely didatic instruction must be reduced to a minimum. This does not present serious difficulties in gross and microscopic anatomy, in pathological anatomy, or in bacteriology; the laboratory technique is comparatively simple and the solution of the problem is merely a question of equipment and an adequate corps of assistants. With physiology the case is different; not only is the apparatus frequently complicated, but the conduct of the experiments themselves often demands an amount of time and technical skill which forbids their introduction into laboratory courses for beginners.

Dr. Porter recognizes this difficulty, and the work before us is his solution of the problem. In the preface he says: "Training in science means first of all the mastery of one field. In physiology the study of nerve and muscle is at present that best adapted to form the mind in habits of exact observation and clear reasoning. Schooled in this important part of physiology, the student can pass more rapidly and with greater understanding over the remaining parts. It is with nerve and muscle, therefore, that the Introduction to Physiology begins, and the treatment of this subject is made as thorough as is practicable."

In general this plan is exceedingly well executed in the work before us. The technique of the nerve-muscle preparation, of the electrical instruments employed in the experiments, and of the graphic method first receives attention. The physiology of nerve and muscle is then studied, as follows: Chapter IV, The Electrical Stimulation of Muscle and Nerve. Chapter V, Chemical and Mechanical Stimulation. Chapter VI, Irritability and Conductivity. Chapter VII, The Electromotive Phenomena of Muscle and Nerve. Chapter VIII, The Change in Form. Each of these subjects is studied by the experimental method, and it is not the least merit of Dr. Porter's book that it points out a practical method of doing this comprehensively and yet with "trustworthy and relatively inexpensive" apparatus. The student observes the facts for the most part for himself, while the explanatory text guides him to the correct understanding of what he observes. In the execution of this sound pedagogical principle the book is eminently and, we may almost say, surprisingly successful.

One point of criticism occurs to us, and that is the omission of all reference to the relation of active muscle and nerve to chemical and thermal change. Surely no one can be said to have mastered the physiology of muscle and nerve without understanding the chemical change involved, for this, with its liberation of kinetic energy, is the fundamental process which is the cause of the change in form, in temperature, and in electrical condition. The defect is all the more striking in the treatment of fatigue (pp. 232 foll.), which is confined to the study of the work done by the fatigued muscle, and makes no mention of waste products, etc. We cannot help thinking that practical laboratory acquaintance with these matters is of more importance to the beginner than many of the electro-motive phenomena which are quite fully considered. The value of the study of the muscle-nerve preparation lies partly in the fact that it is "that best adapted to form the mind in habits of exact observation and clear reason-

ing"; but it possesses even greater value in that it gives us the most convenient means of presenting to the student the action of a typical differentiated organ; and equal stress should be laid upon those features in which all differentiated organs are similar to that laid upon their points of difference. From this point of view the chemical and thermal changes cannot be neglected; if they are, one runs serious risk of leaving with the student the impression that muscle-nerve physiology consists in "making crooked lines on smoked paper."

Part II deals with the mechanics of the circulation and the innervation of the heart and blood-vessels, using the same methods of instruction as in the study of muscle and nerve, and with equally satisfactory results. Especially noteworthy is the efficient use made of the artificial scheme in studying the mechanism of the circulation.

The great value of a course such as that outlined in the present work is that it gives the student an adequate acquaintance with the methods of physiological investigation and enables him to study at first hand and with intelligent criticism other portions of the science. This must ever be of fundamental importance, the first object to be kept in view. The present work is, of course, not final; the next decade will surely see great improvements in our methods of teaching; laboratory work, for one thing, will be brought into more intimate relation with the study of the conditions which obtain in the normal and the diseased human body. Meanwhile Dr. Porter has earned our gratitude for what he has done to bring the student of physiology into more intimate personal acquaintance with physiological knowledge.

Practical Guide to the Public Health Acts (Eng.). By THOMAS WHITESIDE HIME, B.A., M.D. Second much enlarged edition. London: Baillière, Tindall & Cox. 1901.

This excellent handbook has been very much enlarged since the publication of the first edition in 1884. It contains those portions of the General Public Health Act of 1875 which especially concern medical officers of health and inspectors of nuisances, together with very many other sanitary acts down to date.

Still more valuable to sanitary authorities everywhere is that portion of the work which is entitled "Miscellaneous Memoranda of Importance to Medical Officers of Health." In this part of the book is collected a vast amount of practical information upon all subjects relating to public health, meteorology, vital statistics, inspection of meat, school hygiene, etc.

An appendix is also added containing decisions of the courts in 76 cases under the Health Acts.

MANUFACTURE OF ACETIC ACID.— According to the *Philadelphia Medical Journal* acetic acid is now made in Germany from the refuse material obtained from the sauerkraut factories. The enormously increased production will reduce the price of the acid to a merely nominal sum.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MARCH 21, 1901

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE REPORT OF THE ANESTHETICS COMMITTEE OF THE BRITISH MEDICAL ASSOCIATION.

THIS noteworthy contribution to our knowledge of the subject of anesthesia and the comparative value and safety of the various general anesthetics is the result of nine years' work on the part of a committee of twenty-one members of the British Medical Association, appointed in 1891, and having as members such worthy representatives of British surgery as Lord Lister, Professor McEwen and Professor Ogston. The committee was appointed "To investigate the clinical evidence with respect to the effect of anesthetics upon the human subject; and especially the relative safety of the various anesthetics, the best methods of administering them, and the best methods of restoring a patient in case of threatened death." The subcommittee to which this work was deputed, and of which Mr. Hutchinson was chairman, instituted an inquiry which extended over the year 1892 into all cases of the administration of anesthetics in the United Kingdom of which accurate notes could be obtained, and these records were carefully classified and subjected to a most exhaustive and critical analysis. Detailed reports were secured upon 25,920 cases, and the enormous amount of work required in the careful analysis of this enormous amount of material may be imagined. In 13,393 cases chloroform was the anesthetic; in 4,595, ether; in 2,071, nitrous oxide, followed by ether; in 678, A. C. E. mixture; in 418, mixtures of chloroform and ether in various proportions; in the remainder various combinations of chloroform followed by ether, gas and ether followed by chloroform, etc., but it would seem that every possible permutation of these anesthetics and their mixtures had been employed to make up the number of methods investigated to 45. Of the total number of cases analyzed, 25,163, or 97.169% are

classed as uncomplicated cases, or those in which, as far as the effects of the anesthetic are concerned, nothing unusual occurred. The percentage of uncomplicated cases of chloroform anesthesia was 96.73, and of ether 96.953. Of the complicated cases, in 68.57% of the ether cases and 45.2% of the chloroform cases the complications were of a minor character, and not such as to cause anxiety. Out of the 13,393 cases of chloroform anesthesia, 138 cases are classed as cases of danger, and of these 120 recovered and 18 died. The percentage of cases of danger to the total percentage of chloroform anesthesia was then 1.03. Of the 4,595 cases of ether anesthesia there were 14 cases of danger, and of these 8 recovered and 6 died. The percentage of "danger" cases was then to the total ether cases 0.304. This percentage was smaller than that of the various combinations and mixtures, in which, although in some the total number of cases was too small to make the statistics of value, the percentage of "danger" cases ranged from 0.338 to 4.347. There were 29 cases of death due or partly due to the anesthetic, of which 17 occurred under chloroform, 6 under ether, and 6 under other combinations and mixtures.

The analysis with reference to the time of year shows that the percentage of complicated and danger cases was slightly greater in the winter than in the summer months, and that this increase of danger was slightly greater in the case of ether than of chloroform.

The percentage of complicated cases in all anesthetics was greater in males than in females in the proportion of 1.477 to 1, and the percentage of danger cases in the ratio of 1.687 to 1. In males the percentage of danger cases under chloroform was nearly six times that under ether, while in females it was nearly twice the percentage under ether. In males the frequency of danger cases under chloroform was 1 to every 68 administrations; under ether, 1 to 406 administrations. In females under chloroform the danger cases were 1 in every 141 administrations, and under ether, 1 in every 251 administrations.

The analysis with reference to the condition of the patients at time of operation emphasizes the higher danger rate of chloroform in healthy patients. Adding together the cases in which chloroform was used alone or in mixture, a total is obtained of 10,199 patients in healthy condition with 73 cases of danger, or 0.716%. The danger rate in patients in good condition under ether was only 0.135%, or less than one-fifth as great. The exact figures for ether were 5,200 cases, with 7 cases of danger. In patients in poor or very bad condition the danger rate was still higher with chloroform than with ether, but not in so high a proportion.

The analysis of the various pathological conditions as affected by anesthetics brings out many interesting facts, to only a few of which we have space to refer. In valvular disease of the heart the only three cases of danger occurred under chloroform, giving a danger rate of 4.61% for this anesthetic in valvular disease. In tuberculosis, including phthisis, the general danger rate was diminished for all anesthetics, especially ether, while the danger rate for chloroform was less than half the general chloroform danger rate. "Anesthesia in pulmonary phthisis is remarkably free from complications and dangers throughout the whole of the record books." In bronchitis the liability to complications is largely increased, and the danger rate more than five times increased under chloroform. In empyema the general chloroform complication rate was high, but there were so few cases of this disease where other anesthetics were given as to offer no grounds for comparison. In alcoholism, chloroform was found more than eight times as dangerous as in the general run of cases, while in the 56 cases in which ether was employed there were no cases of danger.

To summarize the conclusions on pathological conditions: There was found increased liability to complications and dangers in patients suffering from emphysema, shock and collapse, alcoholism, affections of the heart, emaciation, empyema, bronchitis and anemia. Symptoms of danger were particularly prone to arise under chloroform in emphysema, shock and collapse, alcoholism, diseases of the heart, valvular and otherwise, and empyema.

Many more deductions of interest and value might be cited from this exhaustive and extremely thorough report, but space will only allow us the consideration of a few of the more interesting of the final conclusions of the committee, among which we may select the following as of especial interest:

(1) *Relative safety of the various anesthetics.* — The cases of danger under the chloroform group of anesthetics, considered to be entirely due to the anesthetic, were 88, or 0.584%. Under the ether group of anesthetics there were only 6, or 0.085%. Ether must, therefore, be accepted as the safest routine anesthetic, though certain circumstances connected with the nature of the operation, the state of the patient, etc., may make the use of some other anesthetic or combination safer and easier.

(2) *Methods of administration.* — No method of administration of chloroform is free from danger, but the occurrence of danger depends largely upon the administrator who follows any particular method.

(3) *Regarding chloroform and ether.* — In

conditions of good health chloroform is very much more dangerous than other anesthetics.

(4) When danger occurs under chloroform, there is abundant evidence that in a large proportion of cases the symptoms that are observed are those of primary circulatory failure.

(5) While respiratory complications are, as a whole, of equal frequency under the ether and chloroform groups respectively, yet those which occur under ether are, for the most part, of a trifling and transitory nature, while those that occur under chloroform are more grave and persistent.

(6) While vomiting is more common after administrations of ether, severe and prolonged vomiting is more common when chloroform has been used.

The above are only a few of the interesting and important conclusions arrived at by the committee, a report which may be said to have settled beyond peradventure the relative safety of ether as a routine anesthetic. It will be interesting to note whether it will have any effect upon British practice, or whether chloroform will still maintain its hold.

The results of this laborious clinical analysis and comparison tally very closely with those of physiological experiment, by which repeatedly the limit between the safe and toxic dose of ether was about seven times as great as in the case of chloroform, thus conclusively proving that the former was about seven times as safe an anesthetic for ordinary purposes.

THE STUDY OF ANATOMY.

WITH the growth of the special sciences, there is a clearly discernible tendency toward breadth rather than narrowness. The opponents of specialism would do well to observe this fact, when their pessimism becomes extreme. No sooner does a special branch of knowledge come to the attention of investigators than the full bearings of that branch must of necessity be considered, in determining its relation to the whole body of systematized science. This fact is sufficiently apparent in whatever direction we may turn for an example, but perhaps nowhere more marked than in the study of anatomy. At the outset anatomy was merely a matter of description, and as such might well be regarded as covering a limited field for the exercise of the higher intellectual powers. Later the microscope and the consequent study of tissues in detail, with all the broadening of knowledge which this implies, practically transformed the hitherto descriptive science of anatomy, and led indirectly to numerous relationships with embryology, comparative morphology and many more or less closely related fields of research.

All this means breadth and not narrowness. In fact we may, without looking very far below the surface, see everywhere, with the growth of special knowledge, an inevitable tendency toward a coalition with branches of knowledge often apparently only distantly related. Here, unquestionably, lies the safeguard of what is popularly spoken of as the danger of specialism. Dr. Lewellys F. Barker, of Chicago, in an address to the students of Rush Medical College, published in the *Journal of the American Medical Association*, does a distinct service to the cause of anatomy, by showing its far-reaching associations simply as a pure science. He concludes his remarks as follows: "I have tried to give you an idea of what the study of anatomy includes, viz.: descriptive or systematic anatomy — gross and microscopic — physiological, surgical and topographical anatomy; histology or general anatomy, including histography and cytology; comparative anatomy; embryology; comparative histology and embryology; histogenesis, and, lastly, experimental morphology. Assuredly the subject is wide. It is, I am sorry to say, too wide to be mastered in all its details even when a whole life-time is devoted exclusively to it. The scientific anatomist, after familiarizing himself with the main facts and principles of its various subdivisions, does best, in agreement with the great law of division of labor, to direct his efforts toward the acquisition and promulgation of knowledge in some one portion of it."

MEDICAL NOTES.

DEATHS IN HAVANA, CUBA, DURING FEBRUARY. — According to the vital statistics report from Havana, February 1901, with 408 deaths, is the best record for that month since trustworthy reports have been available. The minimum number was in 1893, with 446 deaths, and the maximum in 1898, with 1,602. This is not only less than any February since 1890, but actually less than any month of the preceding twelve years, the lowest in any month being 444 deaths, in November, 1900. The average for the ten years succeeding 1890 was 746 deaths.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, March 20, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 83, scarlatina 30, measles 79, typhoid fever 3.

BOSTON MORTALITY STATISTICS. — The number of deaths reported to the Board of Health for the week ending March 16th was 236, as against 341

the corresponding week last year, showing a decrease of 105 deaths, and making the death rate for the week 219. The deaths from consumption were 18; pneumonia, 48; whooping cough, 1; heart disease, 25; bronchitis, 9; marasmus, 2. There were 5 deaths from violent causes. The number of children who died under one year was 43; under 5 years, 77; persons more than sixty years, 61; deaths in public institutions, 54.

Great Improvement in Diphtheria Situation at Waltham, Mass. — During the months of October and November, 1900, there were a large number of cases of diphtheria in Waltham. Prompt measures were taken to crush the epidemic. Four physicians were appointed as medical inspectors of schools, but no schools were closed on account of diphtheria. Beside a rigid inspection at school of every pupil much work was done at the homes of those afflicted with the disease. In this way all sources of infection were located and a rigid quarantine maintained. This system proved a success, as shown by the present status of diphtheria in Waltham. The number of new cases has steadily diminished until on March 16th there are no Waltham patients in the diphtheria ward of the Waltham Hospital where for the last few months about two-thirds of the cases have been treated. Inquiry at the Board of Health office shows there are but two convalescing cases in the city at the present time.

Bequest for a Hospital at Newburyport, Mass. — William C. Todd has given the sum of $50,000 and a suitable building site at Newburyport for the erection of a well-equipped modern hospital. The present structure is insufficient to meet the demands made upon it. The new institution will retain the name Anna Jaques Hospital.

Course in Dentistry at Tufts College Extended to Four Years. — The Faculty of the Tufts College Dental School, at its last meeting, passed a unanimous vote to extend the course in that school to four years, the change to apply to all students entering the school in 1902 and thereafter.

A Proposed Hospital at Arlington, Mass. — It is reported that by the will of Stephen Symmes, a resident of Arlington, who died recently, the sum of $25,000 is left to found a hospital in that place.

NEW YORK.

Reversal of an Insurance Judgment. — The Appellate Term of the Supreme Court in the last week in February reversed a judgment for $369.30 obtained in the City Court by Patrick Meehan, a policeman, against a company in which he was insured against accident. The plaintiff lost his left eye and was otherwise injured by carbolic acid which, it was claimed, was thrown in his face by a woman named Marie Pfistler. He was confined in a hospital over ten weeks before he could resume duty. The company contended that, under the terms of the policy, it was not liable for "injuries, fatal or otherwise, resulting directly or indirectly from, or in any wise contributed to by, poison in any form or manner, or contact with poisonous substances." The plaintiff claimed that the policy referred to poison taken intentionally. Justice Blanchard, for the Court, stated that there was a great difference between the words "by taking poison" and "by poison." The former expression might very well be held to mean the internal use of poison, but the latter wording could not be so construed except by a forced construction. "The further contention of the plaintiff," the court said, "that by the subsequent words 'contact with poisonous subtances' is meant and intended voluntary and conscious action of the plaintiff, is likewise without force. In this case the meaning is clear and beyond doubt. The injuries occasioned to the plaintiff were occasioned 'by poison' or by 'contact with poisonous substances' within the meaning of the certificate." Mrs. Pfistler has been twice tried for assault, the jury disagreeing both times. Her story was that the acid was thrown at her by Meehan, and that while she was defending herself with an umbrella the acid was splattered over him.

Anesthetization as a Specialty. — At the monthly meeting of the Medical Association of the Greater City of New York, held March 11th, Dr. S. Ormond Goldan made a forcible plea in favor of anesthetization as a specialty, basing his argument particularly on the ground of the increased safety secured to the patient by having as an anesthetizer one specially skilled in the selection and administration of anesthetics and thoroughly prepared to meet any emergency that might occur. Dr. Goldan's position was fully endorsed by the president of the society, Dr. Robert F. Weir, who stated that while the deaths from ether were commonly placed at one in every 25,000 cases, there could be no question that the percentage was in reality considerable larger than this. He had looked up the records of the New York Hospital (an institution whose reputation, he thought, would compare favorably with others of its class), and found that since the first use of anesthetics there the deaths attributable to ether were about one in 3,000 cases.

Mortality for February. — During the month of February there was a very gratifying falling off in the mortality of the city, which represented an annual death rate of 19.92, against 25.15 in Janu-

ary. The death rate was also considerably smaller than that of February of last year, which was 23.84. In the last week of the month the rate was 27.28 in 1900 and 20.8 in 1901. The most marked decline was in the mortality from pneumonia, the weekly average of deaths from which decreased from 270 in January to 158.5 in February. The weekly average of deaths from influenza decreased from 88.75 to 51.75; from phthisis, from 179.75 to 173.5; from bronchitis, from 54.75 to 41.5; from diphtheria and croup, from 55.5 to 40.75; and from typhoid fever, from 13.5 to 9. On the other hand, the weekly average of deaths from scarlet fever increased from 18.5 to 27; measles, from 1.75 to 6.25; whooping-cough, from 3.25 to 4.5, and smallpox from 2.25 to 8. In the week ending March 2d there were 11 deaths from the last-named disease.

DESTRUCTION OF A SMALLPOX HOSPITAL. — On March 11th a mob, led presumably by the same persons as the preceding one, before mentioned, succeeded in destroying the temporary smallpox hospital at Orange, N. J., chopping it down with axes and hatchets. On the following night the ruins of the building were set on fire and entirely consumed. At a special meeting of the Common Council, called, on March 13th, on the application of the Board of Health, a communication was read from the Mayor, asking the Council to designate a place for the erection of a hospital for contagious diseases, and a resolution was adopted directing the committee on public health to confer with the authorities of East Orange, West Orange, and South Orange in regard to securing a permanent hospital of this character to be used in common by the various communities.

WATER SUPPLY OF NEW YORK. — There has been a good deal of talk about a shortage in the water supply of the city in the near future, but James R. Cross, President of the American Society of Civil Engineers, has just made the statement that there is plenty of water for New York for many years to come, provided the present waste is checked. He bases this opinion principally upon a comparison with Boston, Fall River and other cities, and on the examinations, measurements and observations recently made by John R. Freeman and himself. Roughly, about 61% of the water, he says, is wasted. Of this percentage about one-fifth is wasted by private consumers, and could be checked by the general use of meters. The remainder, or nearly 50% of the entire supply to the city, is wasted by leakage from the street mains and the house connections.

NEW NURSES' HOME FOR PRESBYTERIAN HOSPITAL. — Plans have been filed for a new nurses' home, to be erected for the Presbyterian Hospital on 71st Street, opposite the hospital buildings. It will be eight stories in height, and occupy a plot 124 by 102 feet. Several months ago an anonymous benefactor promised $300,000 for the erection of this building, provided the hospital authorities would assume the maintenance of it. When it is completed the capacity of the hospital will be materially increased, as the upper floors, which are now given up to living apartments for the corps of eighty-five nurses, will then be turned into additional medical and surgical wards.

THE C. R. AGNEW FUND. — In the thirty-first annual report of the Manhattan Eye and Ear Hospital it is announced that during the past year donations and bequests for the C. R. Agnew Memorial Fund have been received to the extent of $2,561, and that this fund now amounts to $24,217.

PROVISION FOR THE SICK POOR. — The Legislature has passed and Governor Odell has signed a bill authorizing town supervisors in counties where there are not adequate accommodations for the care of the sick poor to send such patients to the nearest hospital.

A PROLIFIC FAMILY. — Hester Forbes, who recently died at Waverley, N. Y., at the age of 94, left an extraordinary number of descendants. These are given as 146; namely, 10 children, 50 grandchildren, 72 great-grandchildren, and 14 great-great-grandchildren.

DOUBLE PENIS. — At the March meeting of the Surgical Section of the New York Academy Dr. Carl Beck presented a case of that very rare deformity, double penis; the subject was an infant of five months.

Miscellany.

THE DANGERS OF BOILED MILK.

IT is well, no doubt, says the *Medical Press*, to educate the public in the importance of avoiding the consumption of raw, *i.e.*, unboiled, milk, but it is also well to bear in mind that boiling does not impart to stale or partially-decomposed milk the health-giving properties of freshly-drawn milk. Boiling may sterilize milk so far as active, living organisms are concerned, but it does not rid the fluid of the toxins elaborated by them during their brief spell of life. The irritating effects sometimes observed to follow the ingestion of boiled milk are due, in part at any rate, to the presence of these products. There are, however, other changes to which boiled milk is liable. If raw milk be allowed to stand it turns sour, and the change is accompanied by the production of a certain quantity of gas. If milk which has been sterilized by Pasteurization or by heating to 70° C.

be subjected to the same treatment, the casein is precipitated as curds mixed with bubbles of gas, with a distinctly putrefactive odor. If the milk be boiled before being allowed to stand, the curds fall to the bottom without the formation of gas, and the albuminoid substances undergo gradual disintegration. In the case of raw milk lactic acid predominates; in Pasteurized milk the ferment is destroyed and replaced by gas-forming organisms, while in boiled milk the bacteria are destroyed and their place is taken by peptonizing organisms which elaborate products often of a toxic nature. To prevent this deleterious change it is recommended, when boiled milk is not for immediate consumption, a small quantity of raw milk should be added thereto.

THE INTERNATIONAL CATALOGUE OF SCIENTIFIC LITERATURE.

THE *British Medical Journal*, urging the necessity of an international catalogue, writes:

"One of the complaints which British men of science frequently make is that scientific work done and published in this country is often ignored by foreign investigators and writers. This is even the case with German writers, whose thoroughness in all such work is well known and recognized, and who have frequently laid science under great obligations by the compilation of the bibliographies of special subjects. It is not to be supposed that this failure to recognize work done and published in this country is due to any intention on the part of foreign writers to belittle British science. When attention has been called to such an omission, as it has often been our duty to do, the excuse invariably given is that the foreign writer had not found a reference to the particular research in any quarter accessible to him. The scheme of the International Catalogue of Scientific Literature, as to which we have on several occasions given particulars, is not a British scheme, but it was initiated by the Royal Society, and that body continues to take a leading part in the work. The volumes will, in fact, be published under its direction. There can be no doubt that this catalogue will in future be consulted by all serious workers in all parts of the world who are studying the literature of any subject; it therefore behooves British men of science, in the interest of science itself not less than in that of their own reputation, to take care that the papers which they contribute to scientific literature should be brought under the notice of the cataloguers. If this be not done, there will in the future be no good ground for complaint if publications are overlooked by foreign writers."

Professor Halliburton, writing in the same number of the *Journal*, says:

"The formation of an International Catalogue of Scientific Literature, which was initiated by the Royal Society, and has been the subject of several international conferences during the last few years, has at last been started, and cataloguing is in active progress. It is hoped that all papers published on and after January 1st of the present year will be indexed; the indexes will be two in number—an author index and a subject index. Each participating nation will be responsible for the indexing of the papers published in that country. A central bureau is to collect, co-ordinate, and publish the labors of the various national bureaus."

SUMMARY OF DEATHS IN BOSTON FOR THE YEARS 1899 AND 1900.

THE following statistics, published by order of the Board of Health, offer a comparison of the deaths and the causes for the years 1899 and 1900: Total number of deaths from all causes, in 1899, 11,167; in 1900, 11,678. Population, (estimated) 1899, 555,057; 1900 (census) 560,892. Annual death rate per 1,000 inhabitants, 1899, 20.12; 1900, 20.82. Total number from zymotic diseases, 1899, 1,444; 1900, 3,787. Percentage of deaths from zymotic diseases to total mortality, 1899, 12.93; 1900, 32.43. Total number of still-births, 1899, 539; 1900, 578. Total deaths of children under 1 year, 1899, 2,404; 1900, 2,410. Total deaths of children under 2 years, 1899, 3,034; 1900, 3,013. Total deaths of children under 5 years, 1899, 3,591; 1900, 3,752. Percentage of deaths under 5 years to total mortality, 1899, 32.15; 1900, 32.13. Total number of deaths from diarrhœal diseases, under 5 years, 1899, 329; 1900, 661. Total number of deaths from diarrhœal diseases, all ages, 1899, 396; 1900, 762. Percentage of deaths from diarrhœal diseases to total mortality, 1899, 3.54; 1900, 6.52. Cholera morbus, 1899, 16; 1900, 15. Cholera infantum, 1899, 280; 1900, 299. Cerebro spinal meningitis, 1899. 88; 1900, 66. Diarrhœa, 1899, 69; 1900, 442. Dysentry, 1899, 31; 1900, 6. Diphtheria and croup, 1899, 304; 1900, 537, Erysipelas, 1899, 42; 1900, 53. Influenza, 1899, 49; 1900, 215. Intermittent fever, 1899, 1; 1900. 6. Measles, 1899, 33; 1900, 88. Pulmonary, laryngeal and general tuberculosis, 1899, 1,236; 1900, 1,407. Puerperal fever, 1899, 11; 1900, 29. Pyemia and septicemia, 1899, 73; 1900, 100. Rheumatism, 1899, 17; 1900, 69. Scarlatina, 1899, 74; 1900, 181. Small-pox, 1899, 5; 1900, none. Syphilis (congenital), 1899, 22; 1900, 20. Syphilis, 1899, 5; 1900, 10. Typhoid fever, 1899, 165; 1900, 143. Typhus fever, 1899, none; 1900, none. Whooping cough, 1899, 76; 1900, 99. Yellow fever, 1899, none; 1900, none. Other zymotic diseases, 1899, 9; 1900, 2. Cancer, 1899, 402; 1900, 452. Bright's disease, 1899, 118; 1900, 142. Bronchitis, 1899, 393; 1900, 304. Heart disease, 1899, 966; 1900, 1,009. Pneumonia, 1899, 1,455; 1900, 1,241. Old age, 1899, 212; 1900, 315. Violent deaths, 1899, 620; 1900, 561. The increased number of deaths in the zymotic group in 1900 over that of 1899 is chiefly due to the incorporating into this group pulmonary, laryngeal and general tuberculosis with some form of diarrheal diseases.

METEOROLOGICAL RECORD.

For the week ending March 9th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Date	Barometer	Thermometer.			Relative humidity			Direction of wind.		Velocity of Wind.		We'th'r *		Rainfall in inches.

Deaths reported 2,525; under five years of age 769; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 523, acute lung diseases 468, consumption 285, diphtheria and croup 78, diarrheal diseases 44, scarlet fever 40, influenza 19, typhoid fever 23, whooping cough 11, measles 15, cerebro-spinal meningitis 5, smallpox 10.

From whooping cough, New York, 6, Pittsburg, 2, Boston, 2, Cambridge, 1.

From cerebro-spinal meningitis, Worcester, Haverhill, Gloucester, Everett and North Adams, 1 each. From scarlet fever, New York, 32, Boston, 6, Haverhill and Gloucester, 1 each. From typhoid fever, New York, 12, Pittsburg, 7, Providence, 1, Boston, Chelsea and Fitchburg, 1 each.

From measles, New York, 8, Pittsburg, 5, Boston, 2. From smallpox, New York, 10.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,789,099, for the week ending February 23d, the death rate was 21.2. Deaths reported, 6,718; acute diseases of the respiratory organs, (London) 493, whooping cough 126, diphtheria 77, measles 94, fever 31, diarrhea 33, scarlet fever 26.

The death rates ranged from 11.7 in Burnley, to 27.3 in Liverpool, Birkenhead, 20.6, Birmingham, 25.5, Blackburn, 20.6, Bolton, 17.6, Bradford, 15.6, Brighton, 20.0, Bristol, 23.8, Cardiff, 20.3, Croyden, 14.7, Derby, 19.0, Gateshead, 17.2, Halifax, 20.5, Hull, 24.9, Leicester, 16.5, London, 20.8, Manchester, 26.2, Norwich, 25.1, Nottingham, 22.0, Plymouth, 36.7, Portsmouth, 18.1, Preston, 23.0, Salford, 25.4, Sheffield, 21.9, Sunderland, 22.4, Swansea, 22.4, Wolverhampton, 17.9.

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING MARCH 2, 1901.

PICKRELL, G., surgeon, detached from the Cavite Naval Station, and ordered to the Mare Island Navy Yard.

THOMPSON, J. C., assistant surgeon, detached from the Solace, and ordered home to wait orders.

WENTWORTH, A. R., surgeon, detached from the Independence, and ordered to the Solace.

CORDERIO, F. J. B., surgeon, detached from the New Orleans, and ordered home via the Buffalo.

STOKES, C. F., surgeon, detached from the Buffalo, and ordered to the New Orleans.

ROGERS, F., medical inspector, detached from recruiting duty, and ordered to the Asiatic Station as fleet surgeon.

PERSONS, R. C., medical inspector, detached from duty as fleet surgeon of the Asiatic Station, and home to wait orders.

RUSH, W. H., surgeon, retired, detached from the Pensacola Navy Yard, and ordered home.

SOCIETY NOTICES.

THE AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY. — The society will meet at the New York Academy of Medicine in the City of New York, May 30th, 31st, and June 1st, 1901.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The Section for Obstetrics and Diseases of Women will meet in Sprague Hall, Boston Medical Library Building, 8 The Fenway, Wednesday, March 27, 1901, at 8 P. M.

Papers: Dr. Henry D. Chadwick, "Two Cases of Pregnancy, Complicated by Mitral Insufficiency."

Dr. E. W. Clap, "Albumeneric Retinitis and Amaurosis."

Dr. J. W. Dewis, "A Case of Congenital Pelvic Malposition of the Kidney."

W. H. GRANT, Secretary.
E. S. BOLAND, Chairman.

RECENT DEATH.

EDWARD BRADLEY, M.D., a prominent New York physician, died on March 15, of cardiac disease, at the age of sixty-five. He was born in Burlington, Vt., and was graduated from the Medical Department of the University of Vermont in 1859.

BOOKS AND PAMPHLETS RECEIVED.

Transactions of the Twenty-fifth Annual Meeting of the Alumnae Association of the Woman's Medical College of Pennsylvania, May 17 and 18, 1900. Philadelphia: 1900.

The Students' Manual of Venereal Diseases. By F. R. Sturgis, M.D. Seventh edition, revised and in part rewritten by F. R. Sturgis, M.D., and Follen Cabot, M.D., Philadelphia: P. Blakiston's Son & Co. 1900.

A Treatise on the Diseases of the Ear: Including the Anatomy and Physiology of the Organ, together with the Treatment of the Affections of the Nose and Pharynx Which Conduce to Aural Disease. By T. Mark Hovell, F.R.C.S. (Edin.) M.R.C.S. (Eng.). Second edition. Philadelphia: P. Blakiston's Son and Co. 1901.

Affections Chirurgicales Du Fronc. Mamelles Organes Génitaux de la Femme. Statistique et Observations par le Docteur Polaillon. Paris. 1901.

Address.

THE EMBRYOLOGICAL BASIS OF PATHOLOGY.[1]

BY CHARLES SEGDWICK MINOT, LL.D.

EMBRYOLOGY is the basis upon which pathological science must be erected. Pathology is even more a superstructure upon embryology than is anatomy. Anatomy, in its descriptive form, may stand by itself and have usefulness. Pathology cannot be built up as a merely descriptive science. It fails of its true purpose unless it discovers the causes of diseases. Now, since function is dependent on structure, the aim of the pathologist must be, first, to discover the causes of morbid structure. In brief, pathology at the present time deals chiefly with problems of the development of anatomical forms. Pathology and embryology might almost be united in a single comprehensive study — morphogeny. Let us then try, for this evening at least, to free ourselves from the conception of an essential difference between normal and abnormal structure — a conception which, I believe, domineers too largely over our daily thoughts. This belief of mine I hope to justify tonight.

Simple description is indispensable, it furnishes the virgin facts; but facts do not develop by parthenogenesis into science; they must be saturated with the stimulus of study, with the stimulus of knowledge of their history, their antecedents, their causation; then we may see them evolving themselves into new orders, which we call natural laws. As little as a description of the people of the United States with no information as to their history could satisfy a serious thinker, so little can descriptions of fully developed structures satisfy an earnest pathologist. An innate, intense mental impulse is continually driving us forward in the search for causes, and obedience to this impulse is one of the main factors in scientific progress. All this is familiar, trite even, but may serve to fix our starting thought, namely, that we are to study causes.

Our attention is to be directed to the consideration of what embryology can teach us in regard to the causation of organization, and then to the application of those teachings to pathology. This plan will exclude from our discussion many of the aspects of embryology which appeal most strongly to pathologists. We must omit from our study at least three groups of interesting phenomena, to wit: (1) The arrests of development; (2) the teratological formations, monstrosities and misdevelopments, which will, however, have to be included ultimately even in the precise field we are about to study; (3) the so-called teratoma, or to use a more recent term, "embryoma." I may say in passing that I find it very difficult to accept the hypothesis that these remarkable structures arise by a parthenogenetic development of ova, retained in the parent body. Professor Bonnet's hypothesis is more legitimate, but towards that also my attitude is one of sceptical agnosis. Bonnet suggests that one of the early segmentation cells (blastomeres) may become isolated and retarded in its development, remaining as an inclusion in the fetal tissues, and afterwards develop and produce a variety of tissues, as isolated blastomeres have been shown by experiments on the lower animals to be capable of doing.

Teratological formations fall, it seems to me, naturally into three fairly definite divisions: (1) Those due to necrosis of the tissues, which apparently rarely if ever takes place uniformly throughout the embryo; (2) those due to gross mechanical disturbances of the development, consequent upon failure of the proper correlation of the growth of parts (monstrosities of this division are probably the most common); (3) errors in the differentiation of the tissue, or pathological histogenesis. It is only phenomena of the first and second divisions of teratology which we can safely drop from view, while those of the third division — errors in differentiation — we must bear uninterruptedly in mind.

One more preliminary explanation is necessary. The range of pathological changes is not so great as to reach equality with embryological developments. In the normal embryo we deal with the evolution of complete organs, together with all their accompanying varied and complex modifications of tissue. In pathology, on the contrary, we deal not with organs, but with modifications of tissues, with histogenesis. The statement will not seem too absolute if it is recalled that we have excluded arrests of development and monstrosities from our discussion.

Histogenesis is the common territory in which the pathologist and embryologist have — to borrow a legal phrase — an undivided interest. It is unfortunate that our tendency has so long been to attempt an unnatural and impossible partition of the territory, which has resulted only in a division of our forces into two camps, between which has reigned little interest and less sympathy. I venture to regard your invitation to address you tonight as a wish, which I fully share, to secure fuller co-operation between the two camps of workers, who are both striving to lay bare the laws which govern the differentiation of cells.

After these preliminary explanations it is possible to define the evening's task with precision. It is twofold: (1) To present some of the more important conceptions derived from embryological study in regard to the processes of cell differentiation; (2) to suggest some of the bearings of these conceptions on the problems of pathology.

PART I. NORMAL DIFFERENTIATION.

Under this head I propose to discuss three fundamental ideas: (1) Of the undifferentiated cell; (2) of the progress of differentiation; (3) of the changes which may succeed differentiation.

The fertilized ovum is an undifferentiated being, although it has a very complex organization, and

[1] The Middleton Goldsmith Lecture delivered before the New York Pathological Society, March 26, 1901.

contains, besides the protoplasm, a store of nutritive material, the so-called yolk or deutoplasm. As there is only one nucleus, there can be no variety of nuclei; the term "undifferentiated," therefore, applies to the protoplasm, which seems to have a uniform essential structure throughout, although the masses and strands of protoplasm may exhibit characteristic peculiarities, especially in relation to the distribution of the yolk. In the adult, on the contrary, the protoplasm of the cells of different tissues offers many varieties of essential structure, which can often be readily distinguished under the microscope. It is a legitimate conclusion that the absence of visible peculiarities of the intimate structure of the egg protoplasm, by which one part may be distinguished from another, corresponds to uniformity of structure throughout the egg—excepting, of course, certain special characteristic arrangements, as, for example, the centering about the centrosome, which may occur in any cell.

We have also direct experimental proof that the egg is uniform throughout, or to use a better phrase, that the egg is isotropic. Pflüger, in 1884, proved that the side of the frog's egg which normally develops into the ventral surface of the embryo can be made to develop into a perfectly typical dorsal surface. The frog's egg has a small white area, which normally lies underneath, the larger, darkly pigmented area of the egg alone showing from above. Out of the dark area the back, with the nervous system and other parts, takes its origin. If the eggs, freshly fertilized, are fastened with the white side up, then the white side produces an absolutely normal back and nervous system, normal as to form and function, though lacking the typical pigmentation. These observations were confirmed by Born, who further discovered that the segmentation nucleus always rises towards the upper side of the egg, and that the position of the necleus determines which part of the ovum shall become the dorsal side of the embryo. Another set of experiments by Oskar Schultze demonstrated that both the unpigmented and the pigmented sides of the same egg could be made to produce dorsal structures.

Another class of experiments, which were first made by Hans Driesch, have demonstrated that the earliest cells (segmentation spheres, blastomeres, or cleavage cells, as they are variously called) produced by the ovum preserve the undifferentiated qualities of the parent egg, and may develop in one way or another according to circumstances. The egg of a sea urchin divides into two cells, each of which multiplies and normally gives rise to half [2] of the body of the animal. By somewhat violent shaking the two cells may be artificially separated; each cell may then develop into a complete larval sea urchin, but of half the normal size only. Similar experiments have since been made by several investigators, who have obtained like results with other animals, vertebrate as well as invertebrate. Even more remarkable larvæ have been raised from blastomeres of the four-cell and eight-cell stages of segmentation, producing larvæ of one-fourth and one-eighth the normal size. Zoja claims to have repeated the experiment successfully on the eggs of Clytia and to have obtained one-sixteenth larvæ.

The facts offered suffice to illustrate the two aspects of our conception of the undifferentiated condition of living matter. The first aspect is morphological and presents to us the apparent uniformity of the visible minute structure of protoplasm. While we readily admit that the uniformity may be only apparent in the sense that we fail to observe fine differences, yet we none the less maintain that the uniformity is real, because there is an absence of variations of structure comparable to the variations which we can observe in the cells of adult tissues. The second aspect is physiological and offers to our view the wide range of possibilities in the future developmental history and growth of the protoplasm. The fate of the protoplasm of any given part of the ovum is not fixed, but if its conditions of development are changed its fate is changed. A few years ago the mosaic hypothesis was advanced by W. Roux, and it has been vigorously defended by him. According to the mosaic theory, the egg is a mosaic pattern, each member of which has its predestined history. It is fortunate for our comprehension of pathological processes that we are already able to say that Roux's hypothesis is erroneous.

We must start then with the right conception of the ovum, every part of the protoplasm of which is to be regarded as potentially capable of producing any or all of the tissues of the adult.

We turn next to the consideration of the progress of differentiation, in order to establish a second fundamental idea, namely, that it acts as a progressive restriction of the further development. Each successive stage of differentiation puts a narrower limitation upon the possibilities of further advance. Applied to pathology this law means that the range of possible pathological changes is determined not merely by the nature or kind, but also by the stage or degree of the previous differentiation of the tissue.

The eggs of all animals [3] pass through two well marked phases of development. During the earlier and much shorter phase, the nuclei are multiplying rapidly, while the cytoplasm is growing but little, if at all. This period includes the time of segmentation, as commonly described, and somewhat longer. During this period the total bulk of the nuclei in proportion to the protoplasm is fundamentally changed. The ovum arises from a cell, the ovocyte, which, as its last act, grows rapidly; this enlarged cell by the process of maturation gives rise to the female sexual element, which has a single nucleus. After fertilization we have an ovum with much protoplasm and deutoplasm, but again with only the single segmentation nucleus. The development of each individual begins, therefore, with a cell in which

[2] It would be safer to say supposedly about half.

[3] The protozoa are obviously excluded from the present discussion.

the extreme disproportion between the size of the nucleus and of the whole cell body occurs. The first effort of development is to correct this disproportion by the enormously rapid increase of the nuclei, which continues until cells of the embryonic type are produced, that is to say, cells each with a minimal amount of protoplasm around the nucleus. With the production of cells of the embryonic type, the first phase of development is completed. The limits of this phase are very indefinite, for we observe often that the production of cells of the type defined may be far advanced in one part of the germ, while it is still in early progress in another. In fact the phase has no exact boundary in time.

During the second, later and much longer period, or phase of development, the multiplication of nuclei lags behind the growth of the protoplasm, the increase is gradual and often shows itself through successive generations of cells, sometimes, however, in a single cell, which no longer multiplies. Of the first method of protoplasmic growth, embryonic blood cells offer a good illustration; of the second, the neuroblasts or young nerve cells afford a striking example. Now cells of the embryonic type show little if any capacity for differentiation, and the increase of the protoplasm in the single cell is, so far as we can judge, a necessary preliminary step to cell differentiation. The embryonic cells have yet another characteristic of basal significance — they are capable of rapid multiplication. Hence we conclude that the growth of the cytoplasm impedes the multiplication of cells, and therefore ultimately retards the growth of the body as a whole, while on the other hand it favors differentiation. Accordingly the growth of cells and their differentiation are essentially antagonistic processes, which are necessarily more or less mutually exclusive. This conclusion, which I published in 1890, has since been amply confirmed by further observation. It is probably applicable alike to animals and plants, alike to normal and to abnormal tissues. It is one of the many conclusions of embryology which are sure to throw a revealing light upon some of the dark problems of pathology.

During the first phase of development, as just defined, we encounter preparatory changes which we may characterize summarily as the manufacture of embryonic cells. During the second phase, though the production of embryonic cells is doubtless continued in certain regions, there supervenes the process of differentiation — the true histogenesis.

After segmentation there follows the formation of the germ layers, a gradual arrangement of the cells in three distinct primary strata; at least in all vertebrates there are always three strata, never more[4] nor less. The outer and inner layers, ectoderm and entoderm, very early become distinctly epithelial. The middle layers become partly epithelial, partly of a special character, that is, mesenchymal. At first one is inclined to think of the difference between epithelium and mesenchyma as a fundamental one, an early and unalterable separation of cells into classes. This view finds support in the fact that the mesenchyma, and it only, produces in the course of further development the connective tissue and supporting tissues of the adult. More attentive study of the germ layers in early stages reveals, however, that the mesenchymal cells arise from the epithelium; single epithelial cells migrating from the parent territory, while, on the other hand, groups of mesenchymal cells rearrange themselves so as to form an epithelial covering of some surface, as, for example, in synovial cavities, arachnoid spaces, the inner surface of the cornea, lymph vessels, etc. Such observations teach us that we must not assume that either one form or the arrangement of cells are necessarily and always a sign of true differentiation, but that instead we are to conceive of differentiation as a change in the intimate and essential structure of the individual cell, more specifically of its protoplasm, and perhaps of its nucleus. The rôle of nuclei in histogenesis is a topic which, unfortunately, is still awaiting serious investigation. To resume: It seems to me probable that the cells of the germ layers are at first quite indifferent, so that if it were possible to graft a young mesodermal cell on to the ectoderm or entoderm, it would become a true ectodermal or entodermal cell, as the case might be.

But although we may, so far as we now see, regard the cells in the germ layers as originally wholly indifferent as individual cells, nevertheless we must not forget that as members of a germ layer their potential fate is already restricted by the conditions of their very layership — if I may coin a word for the occasion. Each layer produces its own group of tissues, and never any other. There are indeed apparent exceptions to the rule, as, for example, the stratified, horny epithelium of the esophagus, which is strikingly similar to the epidermis, although in one case the tissue is ectodermal, in the other entodermal. We have, however, to do only with a resemblance, and the development in the two cases is quite unlike — the esophageal epithelium in the mammalian embryo being ciliated at one stage, and exhibiting then little resemblance to any stage of the epidermis.

Each germ layer has its specific function, its exclusive share in the work of differentiation. The work of one layer is not done by another nor shared by another. It is true that attempts are made from time to time to upset the validity of this fundamental doctrine, but they have hitherto failed to find support or recognition from any leading embryologist, and I deem these attempts unworthy of serious consideration. We are able now to assign almost every cell of the normal adult human body to its proper germ layer. Our only great uncertainty is where two layers meet, as do the ectoderm and entoderm in the pharynx, or as do the mesoderm and entoderm, where the ureter opens into the bladder. With these and

[4] Hartwig and some other German embryologists divide the mesoderm into two layers; the division is contrary to the actual development, and is made, in my opinion, quite arbitrarily to satisfy the needs of an erroneous theory.

perhaps a very few other small exceptions, everything in adult anatomy can be correctly stated in terms of germ layers. The layership of every organ is known, save that in the cases of the thymus gland, the tonsils and the adrenals authorities are not yet agreed.

A remarkable attempt to upset the doctrine of the germ layers deserves a brief consideration. It was first maintained by Goronowitch that the cells forming at least a part of the skeleton arose from the ectoderm. The same opinion was expressed also on the basis of their own investigations by H. Klaatsch and by Miss Platt. Confirmation of these views has not followed, but, on the contrary, C. Rabl, one of the most trustworthy of living observers, maintains that essential parts of Goronowitch's and Klaatsch's evidence are simply errors of observation. Klaatsch's views were based partly on the study of the developing teleost fins. R. G. Harrison has shown that here the German worker is in error. Miss Platt's observations were made in the head region of embryo Necturus. An examination of a number of series and stages has not enabled me to find the slightest evidence in favor of Miss Platt's conclusions. H. K. Corning has pointed out that the processes alleged by Miss Platt to occur in Necturus do not take place in the frog, *Rana temporaria*. We may, therefore, I think, safely regard this attempt to overthrow the morphological value of the germ layers as unsuccessful. I know of no other attempt of sufficient importance to be even mentioned.

The importance to pathologists of a thorough knowledge of the genesis of the tissues from their germ layers can hardly be emphasized too strongly, for it is more than probable that all pathological tissues are as strictly governed by the law of the specific value of germ layers as are the normal tissues. Are there not many pathologists whose knowledge of embryology is wholly insufficient to meet the practical needs of their professional study even in this one direction?

The accompanying table presents the principal tissues, classified according to their layership. There have been classifications of organs on the layership basis published before, but inasmuch as organs usually contain cells from two layers, we get a more correct presentation of the actual genetic relationships by restricting our tabulation to the tissues. Leucocytes do not appear in the table for the reason that their first origin is uncertain. Blood cells arise very early, before the clear separation of mesoderm and entoderm has occurred; it is possible that they are entodermal. With these two limitations, the table presents our present knowledge.

CLASSIFICATION OF THE TISSUES.

A. ECTODERMAL.
- (1) *Epidermis:*
  - (*a*) Epidermal appendages.
  - (*b*) Lens of eye.
- (2) *Epithelium of*
  - (*a*) Cornea.
  - (*b*) Olfactory chamber.
  - (*c*) Auditory organ.
  - (*d*) Mouth (oral glands, enamel organ, hypophysis).
  - (*e*) Anus.
  - (*f*) Chorion, fetal placenta.
  - (*g*) Amnion.
- (3) *Nervous System:*
  - (*a*) Brain: optic nerve, retina.
  - (*b*) Spinal cord.
  - (*c*) Ganglia.
  - (*d*) Neuraxons.

B. MESODERMAL.
- (1) *Mesothelium:*
  - (*a*) Epithelium of peritoneum, pericardium, pleura, urogenital organs.
  - (*b*) Striated muscles.
- (2) *Mesenchyma:*
  - (*a*) Connective tissue, smooth muscle, pseudo-endothelium, fat cells, pigment cells.
  - (*b*) Blood.
  - (*c*) Blood vessels.
  - (*d*) Lymphatics.
  - (*e*) Spleen.
  - (*f*) Supporting tissues, cartilage, bone.
  - (*g*) Marrow.

C. ENTODERMAL.
- (1) *Notochord.*
- (2) *Epithelium of*
  - (*a*) Digestive tract, esophagus, stomach, liver, pancreas, small intestine, yolk sack, large intestine, cecum, vermix, rectum, allantois (bladder).
  - (*b*) Pharynx, Eustachian tube, tonsils, thymus, parathyroids, thyroid.
  - (*c*) Respiratory tract, larynx, trachea, lungs.

We will now turn to the analysis of the differential process in each germ layer. We have to deal with changes in cells.

There are two distinct types of cell differentiation, which I think have not hitherto been clearly recognized or defined. For both types the starting point is the same — the undifferentiated embryonic cell. In one type we find that as the cells proliferate a portion of them only undergoes differentiation, and another portion remains more or less undifferentiated and retains more or less fully the power of continued proliferation. The epidermis is a good representative of this type. Its basal layer consists of embryonic cells, which multiply; some of these cells move into the upper layers, enlarge and differentiate themselves into horny cells; others remain in the basal layer and continue to multiply. The progeny of a given basal epidermal cell do not all have the same fate, but divide themselves into two kinds of cells, one kind retaining the ancestral character, the other becoming something new and unlike the parent cell. Differentiation according to the second type is characterized by its inclusion of all the cells. This type has its culminating and most perfect illustration in the central nervous system, where comparatively early in embryonic life all the cells become specialized, and with acquisition of specialization they forfeit their power of multiplication — the neuroglia cells partly, the nerve cells wholly. The growth of the brain after early stages depends not on the proliferation of cells, but chiefly upon the increase in size of the individual cell. The correctness of this statement is not af-

fected, in my belief, by the fact that epithelial portions of the medullary tube in comparatively late stages may be added to the nervous portion, the cells multiplying rapidly, as we see at the growing edge of the young cerebellum. The brain here grows by the addition of cells in the indifferent stage, but as soon as these cells are differentiated, they conform to the general law and divide no more (neurones) or slowly (glia cells).

The two types of differentiation produce essentially unlike conditions. The pathologist may not overlook such unlikeness with impunity. The two types pass into one another with many intergrades. Hence when we consider the possibilities of pathological alteration we must in each case seek to determine how far the condition of the tissue involved permits cell multiplication, as well as differentiation.

Just as the segmenting ovum divides itself into parts, which we name germ layers, each of which has its special and exclusive share in developing the adult tissues, so does each of the three germ layers divide into parts, each part having its special and inclusive rôle, and these parts again subdivide until, after the final partition, the adult variety is produced. During all these changes there is no exchange of rôles. It will be profitable to let the phenomena pass before us in rapid review.

First, then, the ectoderm. This layer early separates into two parts, one to form the central nervous system, the second the epidermis; the nervous part thereafter never forms epidermal structures, the epidermal part never forms a nervous system. The central nervous system retains in part a simple epithelial character, but most of its walls become nervous tissue; its cells pass from the indifferent stage and become neuroglia cells or young nerve cells (neuroblasts). Neuroglia cells never become anything else, and the nerve cells are always nerve cells to the end. The primitive epidermis forms a series of special sensory areas and the permanent epidermis. The sensory areas, which belong to the olfactory, auditory and gustatory organs, soon become well defined and never produce any cell arrangements like those of the epidermis. This last, on the contrary, remains, as before stated, rich in undifferentiated cells, and gradually produces a great variety of structures. Most of these, namely, the hairs and glands, are small and very numerous, while a few, like the nails, enamel organs and epithelium of the lips, are larger. No one of these special structures, however, converts itself into another. The basal layer of the general epidermis may perhaps preserve a true embryonic quality and have wide differential possibilities.

Next, as to the entoderm, which undergoes less differentiation than either of the other two germ layers, since over a large part of its extent it remains throughout life a simple epithelium with many cells very slightly modified in structure. Wherever in it specialization takes place, as in the tonsil, thymus, thyroid, esophagus, liver or pancreas, each territory of cells keeps its characteristics and never assumes those of another territory.

Finally, as to the mesoderm, in which layer variety of differentiation attains its maximum. To follow the genesis of this variety is most instructive. The mesoderm is found very early to include, in vertebrate embryos, four kinds of cells, of which the most numerous are undifferentiated cells, the other three kinds being, (1) endothelial cells of blood vessels, (2) blood cells, (3) sexual cells. All of these are precociously specialized; they are few in number, yet they are probably the parents of all the cells which are produced of their kind throughout life. Our present knowledge does not permit us to speak with entire certainty, but the evidence is strongly in favor of the following three conceptions: (1) That all the endothelium of the blood vessels of the adult is descended directly from the endothelium of the first blood vessels differentiated in the extra-embryonic portion of the germinal area. (2) That all the red blood corpuscles are descendants from the red blood cells of the blood islands of the area vasculosa. According to this view the blood-forming organs, as they are called, merely provide sites where the red cells can multiply, as for instance in the mammalian embryonic liver or in the adult marrow. (3) That the primitive sexual cells by their multiplication produce all the cells from which the genoblasts, or sexual elements proper, male and female, are evolved.

The future will decide the validity of these conceptions. They are very significant, because they assume that there are cells which form exclusive classes, and are characterized by a special combination of qualities, so that while they retain so much of the embryonic character as to have still the power of rapid multiplication, they yet are so specialized that they can only produce their like. If the three conceptions are established, we shall regard these three sorts of cells as almost the first to be fully differentiated. We shall also have to regard the vascular endothelium as distinct not only from the epithelial lining of the body cavity, but also from that of the lymphatic system. The immense importance of such a discovery, as bearing upon pathological researches and interpretations, is obvious.

The next important change in the mesoderm is the development of the main-body cavity, which the embryologist designates comprehensively as the cœlom. The cells, which lie next the body cavity and border it, assume an epithelial arrangement; this epithelial layer around the cœlom is properly named *mesothelium*, and the loose cells about it constitute the *mesenchyma*. We do not have, however, at first, a true differentiation of mesothelial and mesenchymal cells; all are undifferentiated, and we can readily demonstrate that the cells are interchangeable, differing during early stages by their positions in relation to one another and to the body cavity, but not differing in their essential structures or qualities. Thus we find that the mesothelium constantly gives off cells which join the mesenchyma, and we find later that

mesenchymal cells may take on an epithelial arrangement around any of the cavities—and there are many such—which arise within the mesenchyma itself in the course of further development.

But although difference of arrangement does not necessarily indicate differentiation of the cells it does affect the character of the differentiation which ensues. As every textbook states, the mesothelium gives rise to the striated muscles and to the epithelial portions of the entire genito-urinary tract, and is permanently retained, with slighter modifications, as the epithelium of the pericardium, pleuræ and peritoneum. The mesenchyma produces an even greater variety, since it is the parent of not only all the connective and supporting tissue, but also of the lymphatic system.

I venture to turn aside for a moment to urge upon you the adoption of the term "mesothelium" as the correct designation for the epithelial lining of the cavities of the thorax and abdomen. It is literally the same epithelium in the four cavities, for they were originally one with a single continuous epithelium. It is well also in our nomenclature to recognize the important fact that the epithelium is radically, because genetically, distinct from the endothelium of the blood vessels and lymphatics, and the application of the term "endothelium" to the covering of, for instance, the peritoneum, leads and can lead only to confused bad thinking. If mesothelium be employed as suggested, clearness will be gained.

Coming back now to the subject of the mesoderm, let us note that when a striated muscle fibre is produced a striated muscle fibre it always remains, and it never becomes anything else; the ovary never changes. In short, with the mesoderm, as with the ectoderm and entoderm, we see the fate of the cells once fixed to be thereafter unchangeable as to the kind of differentiation.

Our hasty review is worse than imperfect, yet is sufficient to impress upon us the great law that differentiation in any direction terminates the possibility of differentiation in any other direction. In accordance with this law we encounter no instances, either in normal or in pathological development, of the transformation of a cell of one kind of tissue into a cell of another kind of tissue, and further we encounter no instance of a differentiated cell being transformed back into an undifferentiated cell of the embryonic type with varied potentialities.

Thus far I have expressed myself somewhat as if there were two sharply defined conditions, the differentiated and the undifferentiated. To give such an impression would be to create error, since differentiation is a slowly progressive and wholly gradual change in the cell. We must look upon each step in the process of differentiation as establishing narrower limits for future changes. Thus, when in the spinal cord neuroblasts diverge from the glia cells, they are not specialized into different classes of neuroblasts; such specializaton comes later. So in the mesenchyma, after the embryonic cells have changed and large numbers of them have become connective tissue cells, these last still are capable of various further differentiations, and may, therefore, be said to have been arrested in their development at a stage of partial differentiation. This quality of the connective tissue cells is, from the pathological standpoint, one of the most important facts known to us concerning the structure of the body.

Having now elaborated, as far as time permits, our conception of the nature of differentiation, let us turn to our third fundamental idea, which concerns the changes which succeed differentiation. These changes are very unlike the constructive changes, which precede them, for they are destructive. They fall into three main groups: (1) Changes of direct cell death; (2) necrobiosis[5], or indirect cell death, preceded by changes in cell structure; (3) hypertrophic degeneration, or indirect cell death, preceded by growth and structural change of the cell.

Of direct cell death no discussion is here necessary, for the fundamental idea, which I wish to emphasize, is that necrobiosis and hypertrophic degeneration are normal processes, which invariably occur in the normal body and play, in many cases, important rôles in the life history of the individual. Without necrobiosis and degeneration on a large scale, the normal round of human life would be impossible. It is singular that in treatises on normal anatomy and histology these two subjects are generally neglected, or at most appear only as matters of incidental reference. The force of tradition makes us apply these terms as if they corresponded exclusively to pathological conditions. This tradition might still prescribe our mental attitude, were it not that the studies of the last dozen years have made us familiar with the enormous extent, variety and rapidity of the destructive degenerations which go on in the pregnant uterus of placental mammals, a degeneration which takes place without affording a trace or a suggestion of any pathological modification whatsoever of the organ. To our inherited prejudices the uterine phenomena alluded to are startling, but their evidence before the tribunal of biology has settled the case in favor of the plea that hypertrophic degeneration is a normal factor in typical healthy development.

The normal and pathological changes associated with the death of cells, and consequently also of the tissues which are formed by cells, are so nearly identical that they may be combined in a single discussion. For the more convenient presentation of the subject the following table has been prepared. Concerning the table, little explanation is necessary. A few special points need mention. The distinction made between necrobiosis and degeneration corresponds to recognizable differences, but our present knowledge is insufficient to provide clear definitions for the two closely related types of indirect cell death. I feel much doubt as to the propriety of including atrophy in the table at all, since it seems to me that we ought, perhaps, not to regard atrophy as a phenomenon of a distinct

[5] It is a matter for regret that so awkward a term as "necrobiosis" should have become current.

class, but merely as a result of necrobiotic or degenerative alterations in cells and organs. Under the heading "Degeneration" the division into "cytoplasmic" and "paraplasmic" takes us beyond our present knowledge, while the division "nuclear" is added rather to satisfy a biological conscience than to represent a part of our knowledge.

DEATH OF CELLS.

First. Causes of death.
- *A.* External to the organism:
  - (1) Physical, (mechanical, chemical, thermal, etc).
  - (2) Parasites.
- *B.* Changes in intercellular substances (probably primarily due to cells):
  - (1) Hypertrophy.
  - (2) Induration.
  - (3) Calcification.
  - (4) Amyloid degeneration (infiltration.)
- *C.* Changes inherent in cells:

Second. Morphological changes of dying cells.
- *A.* Direct death of cells:
  - (1) Atrophy.
  - (2) Disintegration and resorption.
- *B.* Indirect death of cells:
  - (1) Necrobiosis (structural change precedes final death).
  - (2) Hypertrophic degeneration (growth and structural change often with nuclear proliferation precede final death).

Third. Removal of cells.
- *A.* By mechanical means (sloughing or shedding).
- *B.* By chemical means (solution).
- *C.* By phagocytes.

The preceding table represents the only attempt of the kind known to me, and like other first attempts is undoubtedly very imperfect. It embodies obviously no new facts. But, because it is frequently a scientific gain to systematize our information, I hope the table may be useful, and it will certainly serve its immediate purpose, namely, to guide our discussion of the normal changes which follow after cellular differentiation.

As the time at our command is brief, let us pass by the consideration of the causes of cell death. I will remark only that I think amyloid degeneration may be found to occur in the placental decidua of the human pregnant uterus and perhaps in other normal structures. No positive information on this point is known to me. For the reasons stated a few minutes ago, atrophy may also be omitted here. We pass by also the direct forms of cell death, to reach at once the consideration of the indirect forms.

The accompanying table offers an analysis of some of the principal varieties of structural change, which occur during indirect cell death.

INDIRECT DEATH OF CELLS.

A. NECROBIOSIS.
- (1) *Cytoplasmic changes:*
  - (*a*) Granulation.
  - (*b*) Hyaline transformation.
  - (*c*) Imbibition.
  - (*d*) Desiccation.
  - (*e*) Clasmatosis.
- (2) *Nuclear changes:*
  - (*a*) Karyorhexis.
  - (*b*) Karyolysis.

B. HYPERTROPHIC DEGENERATION.
- (1) *Cytoplasmic:*[6]
  - (*a*) Granular.
  - (*b*) Cornifying.
  - (*c*) Hyaline.
- (2) *Paraplasmic:*[6]
  - (*a*) Fatty.
  - (*b*) Pigmentary.
  - (*c*) Mucoid.
  - (*d*) Colloid, etc.
- (3) *Nuclear* (increase of chromatine).

We begin, therefore, with necrobiosis. We may appropriately mention first those organs of which the existence is limited in time, such as the thymus and the fetal kidney (mesonephros or Wolffian body). These organs attain first their full differentiation; their elements during the next phase die off, and finally are resorbed, most of the organ disappearing. In the same category of change belong the histories of the senile ovary and testis. Another familiar illustration is offered by the notochord, which in the mammals totally disappears during the fetal period. The notochord cells undergo peculiar characteristic modifications, hence it is difficult to say whether or not there is degeneration in the strict sense. Cell death on a large scale is a common phenomenon of the tissues. It occurs in cartilage, both when the cartilage is permanent and even more conspicuously when cartilage gives way to bone, the disintegration of the cartilage cells preceding the irruption of the bone-forming tissues. It occurs among the bone cells after they are imbedded in their calcified matrix. It occurs in the ovary, where we designate its result as atresia of the follicles. It occurs in the sebaceous glands as an accompaniment of the process of their secretion. It occurs among the glands of the intestine, as discovered by Stöhr, and occurs normally, though not constantly, in the appendix, as recorded by Ribbert. It occurs in the epithelium of the human pregnant uterus and in all the tissues of the human decidua reflexa. Other examples could be enumerated, but we may content ourselves with citing the constant destruction of blood corpuscles, both red and white.

Degeneration, in the stricter sense of an antemortem hypertrophic change of cell structure, is also of widespread occurrence in the healthy body. No case of so-called granular degeneration under strictly normal conditions is known to me, though it seems quite credible that such cases should occur. On the other hand, the cornifying degeneration is very important, and does occur in all three germ layers, for we observe it in the ectoderm of the skin, the entoderm of the esophagus and the mesoderm of the vagina. Hyaline degeneration of so striking a character as to have been termed pseudopathological takes place regularly in the ectoderm (outer epithelium) of the placental chorion. In the rabbit it occurs in the uterine glands, during pregnancy, causing most rapid histolysis, and it seems to me probable that some of the changes, which can be observed in the

[6] I cannot venture to assert that these two divisions are valid, and not arbitrary.

decidua of the pregnant human uterus, ought also to be regarded as cases of hyaline degeneration. That fatty degeneration takes place normally has long been taught. There seems no reason for regarding the development of ordinary or mesenchymal fat cells otherwise than as instances of normal degeneration. In old age a more or less marked fatty degeneration may be widespread and occur in many different kinds of cells. The same is true of the deposit of pigment, as we see it in the liver cells and motor nerve cells of adults. Finally, mucoid and colloid degeneration are so obviously normal, that we commonly think of their pathological occurrence as merely an exaggeration of a normal state.

The various kinds of changes in dying cells, with which the pathologist is most familiar, recur in healthy tissues. In the preceding table seven forms of change are enumerated under the heading "Necrobiosis." Every one of these seven occur normally. Granulation of the bodies of the cartilage cells and of the notochord cells may be observed to precede their resorption. Hyaline transformation is conspicuous in the decidua reflexa. Imbibition or cellular œdema occurs in the epidermis of the lips, in the cells of the uterine glands during pregnancy, after they have detached themselves from the gland walls, and in the endothelium of the placental blood vessels of the rabbit. Desiccation is the usual accompaniment of cornification. Clasmatosis has given its name to the clasmatocytes of Ranvier, and we may well apply the same term to the cells of the secreting milk gland, and also, as an unpublished research indicates, to the cells of the secreting glands of the cervix uteri. Karyolysis is, according to present probabilities, the method by which nucleated red blood cells are converted into non-nucleated blood corpuscles. Karyorhexis, or the fragmentation of the nucleus, occurs in the cells of the disappearing follicles of the ovary.

Lastly, as to the removal of cells. The sloughing off of cells is one of the most familiar phenomena, since it occurs incessantly over the epidermis and with the hairs; its part in menstruation and its colossal rôle in the after-birth are known to all, and every practitioner is accustomed to look for shed cells in urinary sediment. Large numbers of cells are lost by the intestinal epithelium. Cells without access to the external world must be got rid of by resorption, which seems to take place either with or without the co-operation of leucocytes. In the latter case we must for lack of a better hypothesis attribute the resorption to chemical means. Of resorption with the aid of leucocytes the necrosed human decidua reflexa offers a perfect illustration. Of resorption without leucocytes the masses of degenerated epithelium in the placenta, periplacenta and obplacenta of the rabbit afford by far the most impressive demonstration I have ever seen. At nine days after conception the epithelium is profoundly changed, being very much thickened, and where thickened transformed into a syncytium without cell boundaries, but with an enormously increased number of nuclei. In the obplacenta (or portion of the uterine wall opposite the placenta proper) portions of the epithelium from the fundus of the glands remain, but the upper stratum has not only undergone syncytial degeneration, but has become vacuolated and partly resorbed without being directly attacked by either leucocytes or epithelium or any other kind of cells. At eleven days the resorption has progressed still farther, so that the degenerated part is almost gone, but meanwhile the isolated patches of epithelium have spread until they united and so reformed a continuous epithelium. At thirteen days the epithelium has reconstituted new glands or follicles, very unlike, however, those of the resting uterus. To explain the extraordinary rapid disappearance of the degenerated material in the obplacenta, the only available hypothesis seems to be that of a chemical change by which the material becomes soluble or is dissolved, for we see the disappearance of the substance taking place in the very heart of the layer, and not merely at the surface. Sloughing is impossible, and there are no phagocytes, leaving the chemical explanation as the only one I have been able to conceive. The contemplation of the described phenomena of the rabbit's obplacenta inevitably raises the question — do we not tend in our explanations of the removal of necrosed and degenerated tissues to attribute too much to phagocytes and too little to direct chemical action? May it not be that the body produces histolytic toxins, which can destroy tissues somewhat as do snake-poisons.

The cycle of changes through which cells pass is obviously longer than the period of development and the differentiation, yet its phases all belong together as members of a single series. We lack a word to designate the entire series of changes, and for the lack of such a word often fail to appreciate the essential unity of progressive and regressive modifications of cell-structure. Accordingly, I wish to propose the new term, "cytomorphosis," to designate comprehensively all the structural alterations which cells, or successive generations of cells, may undergo from the earliest undifferentiated stage to their final destruction.

PART II. PATHOLOGICAL DIFFERENTIATION.

We have now completed our brief reviews of the four fundamental successive stages of cytomorphosis. These stages are: (1) Undifferentiated; (2) progressive differentiation, which itself often comprises many successive stages; (3) regression (necrobiosis or degeneration); (4) removal of the dead material.

Let us now apply some of the conceptions won to the interpretation of pathological differentiation, remembering all the time that the interpretation of diseases is a distinct and different problem. Although presumably pathological differentiation is the sole and exclusive cause of disease, and no disease arises from any other immediate cause, yet the disease must be regarded as the result, and, owing to the physiological correlation of the organs, this result may include many sec-

ondary effects, some of which are often of the greatest diagnostic value, and therefore likely to divert attention from the primary structural cause.

Our review of normal conditions furnishes us with three general conceptions, which are valuable for their pathological applications, namely: (1) That each germ layer has a specific and exclusive share in the production of tissues; (2) that undifferentiated cells, characterized by having only a small amount of unspecialized protoplasm, exist not only in the embryo, but also throughout life in certain parts of all three germ layers; (3) that differentiated cells, characterized by having a larger amount of specialized protoplasm, form most of the organs of the adult, and are incapable of undergoing any new unlike differentiation, though they are still capable of completing their cytomorphosis, by necrobiosis or degeneration.

We must apply these conceptions, according to my belief, as rigidly to pathological as to normal development. Thus, as to the germ layers, it ought to be possible, even with our present knowledge, to show their pathogenetic values, so that every elementary student, as a matter of course, can be taught to classify accurately most pathological differentiations, and to accept such a classification as the basis of all his further study of the science. How much this reform is needed is indicated by the many writers who put glioma under the head of connective tissue tumors, although gliomata arise from the ectoderm, and connective tissue arises from the mesoderm. Such a classification is on a par with the ancient system, which put the whales among the fish, for it is not going too far to say it is impossible that connective tissue should produce a glioma, because the two things belong in different classes. Another noteworthy violation of embryological law is offered by the classification of all muscle tumors under one head, "myoma," although smooth and striated muscle fibres are genetically and structurally distinct, with no intermediate or connecting forms of tissue, and with only a slight physiological resemblance. As regards epitheliomata, they should be studied in relation to their layership; and it is reasonable, in my judgment, to expect that they will be found to have very distinctive characteristics, according to the germ layer from which they take origin, for the layership of a tissue governs the normal differentiation and therefore probably also the abnormal. I believe that the first competent investigation in this field will mark a new epoch of pathological science. When that epoch comes our morphological sense will no longer be shocked, as for instance by the application of the name adenoma to an epithelioma of an organ like the kidney, which is in no sense a gland.

I should like to urge especially the study of the layership of the various cancers. Can we safely assume that there is only one kind of cancer? May it not well be that ectodermal, mesothelial and entodermal cancers are separate kinds?

Next, as to undifferentiated cells. The cells of this sort have the power of multiplication in a high degree, and they have the possibilities of increasing their size and of undergoing further differentiation, and their occurrence in the adult is of the utmost pathological significance. Such cells exist in four important parts: (1) In the basal layer of the epidermis and in corresponding portions of the epidermal appendages; (2) in the adult mesenchyma or connective tissue; (3) in many parts of the adult mesothelium, especially of the epithelia of the genito-urinary tracts; (4) in the entodermal epithelium of the gastro-intestinal tract. It is significant that it is precisely from these parts that the development of many rapidly growing tumors takes place, and it is further significant that the least differentiated or specialized of all, namely, the mesenchymal cells, are the ones which produce the greatest variety of tumors, as the following list recalls: myxoma, myoma (but not rhabdomyoma), fibroma, lipoma, chondroma, osteoma and sarcoma. Angioma presumably belongs in a different category. The mesenchyma still exhibits, by the formation of its characteristic tumors in the adult, its embryonic capacity to transform itself in varied ways.

Further insight into pathological development may be gained from the tissues or cells which have undergone differentiation, but do not attain a high grade of specialization. The endothelium of blood vessels, the endothelium of lymph vessels, the red blood cells, the leucocytes, and the neuroglia are examples of this class. All the cells of the kind just enumerated have advanced in organization beyond the embryonic state, but have retained the power of cell multiplication. When they multiply they produce cells like themselves, so that we might describe them as so many histological species, each capable of reproducing its own kind. In accordance with this conception, derived from the normal development, is the pathological fact that each of these species of cells produces tumors of its own kind. This is a familiar conclusion as regards the endothelium, both of the blood vessels and of the lymph vessels, and also as regards the neuroglia. It seems to me that the excessive multiplication of leucocytes may properly be classed in the same category as the growths resulting in angioma and glioma. I do not know whether or not an excessive and abnormally rapid production of red blood cells may occur so as to occasion a special and distinct disease. Increased production of red blood cells (erythrocytes) is, of course, well known to occur, but I understand that a distinct disease of this origin is, as yet at least, not recognized. It is not improbable, however, that such a disease exists, — we should, I suppose, name it *erythrocytosis* or *hematoma*.

We can now distinguish two main groups of new formations: (1) Those with marked cytomorphosis, or change in cell structure, as, for example, myoma, lipoma, chondroma, etc.; (2) those without marked cytomorphosis, the cells of the new growth resembling those of the parent tissue, as for example, angioma and glioma. Members of

the first group have been termed *heteroplastic*. Members of the second group have been termed *homoplastic*.

Accepting these terms we may say tumors are either *heteroplastic* or *homoplastic*. From the standpoint of the embryologist these terms are much more than convenient adjectives; on the contrary, they denote differences of a fundamental character, upon which we must base a large part of our notions about pathological differentiation.

Finally, as to the differentiated cells. We have just considered cells which have reached a low degree of differentiation, and therefore will now give our attention only to the most highly differentiated. Of these the nerve cells, or, as they are now termed, the neurones, stand highest, and are characterized not only by the great specialization of their organization, but also by the complete loss of their ability to multiply by cell-division. The neurones are then extremely unlike the embryonic cells, and they represent the extreme end of that scale of which the undifferentiated cell is the beginning. It is, therefore, very significant that neurones do not form tumors. Neuronoma, as such a tumor would be called, does not occur, so far as hitherto recorded, and if, as is possible, a neuronoma should be found, we should have to explain it not as a tumor-growth of neurones, but as the result of proliferation of indifferent cells, which subsequently became differentiated into neurones. The so-called neuromata of pathologists do not here come into consideration because they are merely accumulations of growing axis cylinders.
